THE fifth annual exhibition, which was held by the Physical Society of London at the Imperial College of Science and Technology last week, was marked by some pleasing innovations. Hitherto the exhibition has been limited to the evening only, but on this occasion it was open also in the afternoon, and this extension of time was evidently appreciated. Experimental lectures were also introduced. Thus many visitors must have welcomed the opportunity of seeing once again the beautiful and well-known experiments on soap bubbles by Prof. C. V. Boys, F.R.S., as they have not been seen during the last ten or fifteen years. In the evening Prof. S. P. Thompson, F.R.S., showed the remarkable effects obtained by combining mica and selenite viewed under polarised light.

Turning to the exhibits themselves, we may remark that there were about forty exhibitors, and for this reason it is impossible to do more than give a brief reference to some of the more interesting and novel exhibits in the space at our disposal. In the subject of mechanics, in its broadest sense, Mr. W. V. Gilbert's anticlastic levers, shown by Messrs. Strange and Graham, received the most attention. The device is known by the trade name of "Vilcars," and enables a movement in a given plane to produce a movement in a plane at right angles, although no joints or complicated links are used for producing this change in the direction of motion.

Among other mechanical devices we may mention the Wimperis accelerometer, shown by Messrs. Elliott Bros. (see NATURE, December 2, p. 139). The acceleration is indicated by a pointer, which moves on a scale suitably graduated. The indication is effected by an eccentrically placed copper disc which is controlled by a hairspring and is magnetically damped. By a special gear and balance weight the disc is compensated so that the instrument is affected only by acceleration in one direction, which is indicated by an arrow on the dial. A simpler type of instrument is that due to Mr. A. P. Trotter, and shown by Messrs. Everett, Edgcumbe and Co. This consists simply of a curved glass tube nearly filled with liquid, and is best described as a spirit-level of extravagant curvature. When subjected to acceleration along its length the position of the bubble varies according to the acceleration. Obviously it may be used equally for measuring gradients.

The principle of the diffusion of gases is brought into practical use in the gas-leakage indicator shown by the Cambridge Scientific Instrument Co. An elastic metal chamber is closed by a porous tile, so that the pressure within it increases when the instrument is brought into an atmosphere containing light gas, such as coal gas. The pressure is shown by a pointer, the motion of which is an indication of the presence of gas.

There was a good display of optical apparatus, including microscopes, cameras, and photometers. Among the latter may be mentioned the daylight illumination photometer due to Mr. A. P. Trotter, and exhibited by Messrs. Everett, Edgcumbe and Co. In testing the illumination of a room by daylight, an absolute figure in, say, candle-feet is not of value by itself, because it depends upon the brightness of the day on which the measurement is made. This difficulty is overcome by using a vertical tube placed over the screen which receives the illumination to be measured. The instrument is first placed where a clear view of the zenith is obtained, and a stop is inserted in the tube so as to cut down the illumination to a convenient figure. A measurement is then made in the room where desired, the tube having been removed. The stops are so proportioned that the true ratio of the illumination in the room to that in the open is readily obtained. As examples of such measurements the makers mention that the ratio over the Speaker's chair in the House of Commons is 0·0009, and that in the British Museum reading room 0·007.

Electrical exhibits were by far the most numerous, and among these perhaps the most interesting was the application of Abraham's rheograph (shown by the Cambridge Scientific Instrument Co.) to throw on the screen a hysteresis loop. It will be remembered that in the rheograph a light aluminium frame is suspended in a permanent magnetic field, and forms the secondary of a small transformer. The controlling and damping forces are made relatively unimportant, so that the deflection becomes proportional to the current or potential difference under observation. On the present occasion two vibrators were arranged at right angles, one to give a deflection proportional to **B** and the other to **H**. A beam of light being reflected first from one and then from the other therefore gave a hysteresis loop, which appeared quite steady upon the screen.

The same firm showed Dr. C. V. Drysdale's slip meter, which, although it has been in use for some years at the Northampton Institute, has not, so far, been generally available. A circular card, on which certain geometric figures are printed, is fixed to the shaft of the machine under test, and is observed through a stroboscopic disc. The latter is driven frictionally by a conical roller, which in turn is driven by a small synchronous motor. By moving the disc along the roller its speed is varied, and when the geometric figures on the card appear stationary the speed can be read off on the graduated leading screw which controls the position of the disc. This part of the apparatus is quite small and compact. Depending on the arrangements used, speed, frequency or slip can be determined.

Messrs. Snell and Tinsley showed one of Dr. C. V. Drysdale's potentiometers for alternating currents, the difficulty of phase difference being eliminated by a "phase shifter," by which the phase of the current in the potentiometer wire is made to coincide with that of the pressure to be measured. A rotary field is produced in the phase shifter by splitting up a single-phase current into two in quadrature.

Duddell's vibration galvanometer, which is a modified oscillograph, was shown by Messrs. Nalder Bros. and Co. Messrs. J. J. Griffin and Sons exhibited Mr. Tucker's high-potential primary battery; it is compact in form, and appears to give its 1000 volts with a minimum of trouble. Mr. F. Harrison Glew showed a radium collector for atmospheric electricity. This consists of a metal spiral coated with insoluble radium salts; it is suspended in an elevated position from a weather-proof insulator, and as the radium ionises the air around it the wire acquires the potential of the atmosphere, and gives an indication on an electroscope.

Visitors also had an opportunity of seeing one of the latest methods of transmitting photographs electrically, as exemplified in the apparatus of Mr. T. Thorne Baker, shown by the *Daily Mirror*. Prof. Korn's method, with selenium cells, has reached a stage of some perfection, but the smallness of the currents available in such a method introduces difficulties. There is thus a tendency to use rather more mechanical methods. In Mr. Baker's apparatus, photographs are printed on fish-glue upon lead foil, and lines are drawn across this so as to expose the lead. The style comes into contact more or less with the lead, depending upon the density of the image, and thus allows current to flow into the line. At the receiver the picture appears on suitably prepared paper by electrolytic action, and the results seem to be very satisfactory.

The exhibits we have enumerated by no means exhaust all that was of interest, but want of space renders a complete survey impossible.

EXPERIMENTS ON COMPOUND STRESS.

TWO papers dealing with experiments on compound stress were read at the Institution of Mechanical Engineers on Friday, December 17. The first of these, by Mr. William Mason, of the University of Liverpool, gave the results of tests made by the author on mild steel tubes, and included tests made in simple compression, in simultaneous compression and hoop tension, in simple axial tension, simultaneous axial and hoop tension, simple axial compression, and simultaneous axial and hoop compression. Two sizes of tubes were used, viz. 3 inches bore and 2·75 inches bore, of thickness about 0·08 and 0·128 inch respectively. The larger tubes were cold-drawn, and the others were hot-drawn. Some of the tests were made on the tubes unannealed, in others the tubes were annealed. Extensometers of the Ewing type were used in measuring the strains. The testing machine employed was the 100-ton Buckton machine in the Walker Engineering Laboratory. Hoop tension and compression were obtained by applying hydraulic pressure to the inside and outside of the tubes respectively; in the latter case a special jacket surrounded the tube under test. The experiments show an approximate agreement between the maximum shear stress at the yield point in compression and the yield-point stress in pure shear, the mean difference in the tests of annealed specimens being about 3 per cent. It appears, then, that mild steel in compression yields by shearing; and, to a first approximation, the value of this shear stress is independent of any normal compressive stress on the planes of the slide.

The second paper was contributed by Mr. C. A. M. Smith, of the East London College, University of London. Solid mild steel test specimens were used under combined tension and torsion, and also under combined compression and torsion. The 50-ton machine at the college was used, and the strains were measured by means of the author's sphingometer, by means of which readings are obtained on three planes at 120 degrees. The results obtained give further confirmation of Guest's law for mild steel. The author's remarks regarding the difficulty of obtaining axial application of the load, both with pull and push, were of special interest. Ordinary wedge grips are of little use in securing this; even spherical seatings are bad. Sphingometer readings with the latter show great divergence from regularity in the strains on three planes, although the means are perfectly regular. Often in a test the ball joints slip into new bearing positions, thus producing a new eccentricity of the load. These facts emphasise the necessity of employing an instrument of the sphingometer type in tests of a scientific character for loads within the yield point.

THE PARASITES OF THE GROUSE.

SOME valuable results of the work of the Grouse Disease Inquiry Commission are published by Dr. A. E. Shipley, F.R.S., in a series of papers on the parasites of the red grouse (Proc. Zool. Soc. Lond., 1909, pp. 309–368, plates xxxv.–lx.), in which the ectoparasites, the thread-worms, and the tape-worms are successively described and illustrated.

Ninety per cent. of the birds examined were infested with two species of Mallophaga (*Goniodes tetraonis* and *Nirmus cameratus*) which feed on the barbules of the feathers. "The number on each bird is to some extent an inverse measure of their health." Though not a parasite, the larva of the common dung-fly (*Scatophaga stercoraria*) is described and excellently figured—a noteworthy contribution to the scanty literature on larval Diptera—because it was hoped that these maggots, which are found in numbers among the droppings of the grouse, might prove to be intermediate hosts for the grouse tape-worms; the results, however, were entirely negative. With the same object in view, the crops of many grouse were examined, and although gamekeepers and sportsmen believe that these birds eat no insects, their animal food was, in fact, found to be "fairly abundant and very varied," comprising caterpillars of moths and saw-flies, frog-hoppers and Diptera, spiders and slugs. Although no bladder-worms were found by these investigations, Dr. Shipley has incidentally thrown light on the feeding habits of the grouse, and has shown that mere external observation in such questions is often to be distrusted.

The grouse tape-worms, the cysticercus stages of which are thus still unknown, comprise a larger species (*Davainea urogalli*) and a smaller one (*Hymenolepis microps*). This latter, "so transparent when alive as almost to be invisible," is nevertheless very abundant in the duodenum, where its presence appears to be often fatal to the birds, so that it is a far more serious pest than its larger companion.

Of the Nematoda that infest the grouse, *Trichosoma longicolle* and *Trichostrongylus pergracilis* are the most important, and the latter of these, at least, requires no intermediate host for its development. By soaking heather and then centrifuging the drawn-off water, Dr. Shipley showed that "heather is, so to speak, crawling with thread-worms"; the means by which the nematode larvæ, hatched from eggs passed out of the birds' intestines, enter the food canal of new hosts is thus plain. Another fact of interest is the presence of larval thread-worms in the lungs and liver; these are believed to be derived from eggs hatched while still in the intestine of their parents' host-bird, and to wander through the latter's body. Readers who have followed Dr. Shipley's recent suggestions as to the importance of parasitic worms in certain human diseases will be prepared for his belief that these wandering larval nematodes may be responsible for pathological conditions in the organs of the grouse.

G. H. C.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The general board of studies has appointed Mr. L. A. Borradaile to be university lecturer in zoology from January 1, 1910, to September 30, 1914.

It is proposed, in accordance with the recommendation of the special board for moral science, to appoint a syndicate to make arrangements for the building of a laboratory of experimental psychology.

DR. J. L. SIMONSEN, assistant lecturer and demonstrator in chemistry in the University of Manchester, has been appointed professor of chemistry in the University of Madras, and Dr. A. Holt has succeeded him at Manchester.

A LECTURE by some man eminent in letters, science, or art, to be delivered annually in the Lent term, has been established at Queen's College, London. Her Majesty the Queen, patron of the college, has allowed it to be called the Queen's lecture.

UNDER the Irish Universities Act, 1908, graduates of the Royal University of Ireland may be registered as graduates of the National University of Ireland. We are asked to announce that as the first meeting of Convocation must take place within six months from the date of the dissolution of the Royal University of Ireland, it is very advisable that application for registration as graduates should be made without delay. All information may be obtained from Dr. Joseph McGrath, registrar of the University, the National University of Ireland, Dublin.

COURSES of afternoon lectures on aëronautics will be held after Christmas at the Imperial College of Science and Technology. Sir George Greenhill, F.R.S., will lecture on the dynamics of an aëroplane; Mr. H. R. A. Mallock, F.R.S., on fluid resistance; and Colonel H. C. L. Holden, F.R.S., on light petrol motors for aërial work. The courses will begin respectively about the middle of January, the early part of February, and after Easter. Research scholarships will be awarded by the college to advanced students desirous of undertaking research work in scientific problems connected with aëronautics. The scholarships are to be tenable for one year at the Imperial College, and provision may be made for part of the work to be undertaken at the National Physical Laboratory. Scholars will be entitled to free admission to the college and to a maintenance allowance.

THE next annual conference of teachers arranged by the London County Council will be held on January 6–8 inclusive at Birkbeck College, Chancery Lane, London. Among the subjects for discussion, we notice that during the afternoon of the first day the training of engineers will be dealt with. Sir William White, K.C.B., will preside, and addresses will be delivered by Prof. D. S. Capper on the training of engineers, by Dr. R. M. Walmsley on the sandwich system as applied to day engineering students, and by Mr. R. Bunting on higher elementary education and the preliminary training of engineers. The next afternoon Sir Lauder Brunton will preside, and the teaching of domestic economy will be discussed. Mr. John Wilson will deliver an address on the correlation between the teaching of domestic economy and experimental science. Other subjects of discussion will be:—the organisation of higher schools; the teaching of number; methods of teaching in schools for the mentally defective, and educational experiments in schools. No charge is made for admission, and tickets may be obtained from the Chief Inspector, Education Department of the London County Council.

LA LIGUE DU L'ÉDUCATION FAMILIALLE was founded in 1899, with the cooperation of the Belgian Government, to secure closer association between parents and teachers in the study and practice of educational methods. An international congress was held at Liége in 1905 to discuss the relationship of home life to education in school and college. A second similar congress was held in Milan in 1906. At the request of the Belgian Government a committee has been organised to bring to the attention of the British public the third International Congress, to be held in connection with the Brussels Exhibition, August 21–25, 1910. The Marquess of Londonderry has accepted the presidency of the committee, and Mr. Walter Runciman, President of the Board of Education, and Mr. Charles Trevelyan, Parliamentary Secretary to the Board, have been appointed vice-presidents. The necessity for intimate association of home and school influences if we are to obtain efficiency in education is becoming increasingly recognised, and the committee desires that parents and teachers will take full advantage of such an interchange of opinion as is offered by this congress.

THE prize distribution at the Imperial College of Science and Technology, South Kensington, on Thursday, December 16, was chiefly noteworthy for the interesting address by Prof. Sedgwick, F.R.S., on scientific research, reprinted in another part of this issue. Lord Crewe, the chairman of the governing body, presided, this being the first occasion on which he has attended this annual function. In his opening remarks the chairman referred to the resignations of the rector (Dr. Bovey), Sir William Tilden and Prof. Gowland. The proceedings were enlivened by numerous interruptions from students of the Royal School of Mines, who, by shouting the name of the school, demonstrated that the individuality of the school has not been lost by the establishment of the Imperial College, of which it forms an "integral part." The vote of thanks to Lord Crewe for presiding was proposed by Sir Julius Wernher and seconded by Mr. Arthur Acland, who stated that the governing body has set aside the sum of 12,000*l.* for the establishment of a students' club. Lord Crewe, in responding, appealed for a double loyalty among the students—for their respective colleges on the one hand, and for the Imperial College on the other, the relation of which to the component colleges he compared to that of his own University of Cambridge to the Cambridge colleges. The associateship of the Royal College of Science was granted to forty-four students, and the associateship of the Royal School of Mines to thirty-four students.

THE Mathematical Association and the Association of Public School Science Masters will hold their annual meetings next January in common, to a large extent. The meetings of both associations are to be held at Westminster School. On January 12, 1910, the Mathematical Association will hold its own meeting in the morning, when, after the business part of the agenda has been completed, addresses will be delivered by Mr. C. Godfrey on different methods in algebra teaching for different classes of students, by Prof. P. J. Harding on elliptic Trammels and Fagnano points, and by Mr. W. J. Dobbs on a patent inexpensive balance. During the afternoon of the same day a joint meeting will be held of both associations for the consideration of the report of the committee on the correlation of mathematical and science teaching. On January 13 the science masters will hold their annual meeting. The president for the year, Prof. H. E. Armstrong, F.R.S., will deliver his address, taking for his subject "The Future of Science in Our Schools." Afterwards Mr. Eccles, of Gresham's School, Holt, will read a paper dealing with the confusion existing in the symbols used in text-books on physics, and urging that some uniform system be introduced. In the afternoon Mr. L. Cumming, of Rugby School, will read a paper on the desirability of teaching all boys geology or biology during some portion of their school life; Mr. Cross, of King's School, Peterborough, will deal with laboratory equipment and design, and Mr. Oldham, of Dulwich College, on teaching oxidation and reduction. The usual exhibition of books and apparatus will be held.

THE annual prize distribution of the Sir John Cass Technical Institute was held on December 16, when the awards were distributed by Dr. H. A. Miers, F.R.S., principal of the University of London. In the course of his address, Dr. Miers pointed out that success in competition is to be regarded as a special gift, because it is not everyone who is born to succeed in competing with his fellow men and women, and, moreover, success is not to be measured by the faculty of excelling others. No pleasure can surpass that of success in one's own work, and the problem in modern life is how to combine this conscious spirit of pleasure and pride in work with the totally different conditions in which it is carried out now as compared to those which existed in the old days of the guilds and apprenticeship in the City of London. The aim of technical institutions should be to make the students less of specialists and to give them more versatility and adaptability so as to enable them to find out new ways of pursuing their own work. It is true that in order to effect this many subsidiary subjects of study are necessary, but such subjects should be regarded as only representing the different principles of the more special subject of study, and should be worked out with enthusiasm and keenness from the point of view of their bearing upon the specific science or industry in question. New methods of work which may have a bearing in many directions of science are not made as accessible as they should be, owing to the extreme difficulty of reading research papers outside one's own special subject, a difficulty due to the fact that those who are pursuing scientific research and are studying scientific methods do not devote sufficient attention to expressing themselves in simple English. The student who goes out into the world with a keen interest, not only in his special work, but also in the other subjects which he had to learn as a student, and with some knowledge of the general principles underlying them all, will never feel helpless when he finds himself in new conditions and confronted by new problems. In conclusion, Dr. Miers pointed out that no educational work could be quite successful unless it is inspired by the spirit of research, and he welcomed the encouragement of research in the Sir John Cass Technical Institute, referring especially to the prizes awarded by the Goldsmiths' Company in metallurgy, and to the award by the Institution of Mining and Metallurgy of the "Consolidated Goldfields of South Africa premium of forty guineas" jointly to Mr. C. O. Bannister, the head of the metallurgy department, and to Mr. W. N. Stanley, a student in the department.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 9.—Sir Archibald Geikie, K.C.B., president, in the chair.—W. J. **Young**: The hexosephosphate formed by yeast-juice from hexose and phosphate.—L. S. **Dudgeon** and H. A. F. **Wilson**: On the presence of hæm-agglutinins, hæm-opsonins, and hæmolysins in the blood obtained from infectious and non-infectious diseases in man (third report). These results are based upon some hundreds of experimental observations which have been made upon normal and pathological blood, and are as follows:—(1) Auto-agglutination of the red blood cells, as tested for by the methods which we have employed, may be shown to occur with specimens of pathological blood only occasionally, but never with normal blood; and auto-hæmolysis has not been met with. (2) Iso-agglutination is often met with in specimens of blood obtained from patients suffering from the same disease. (3) Hæm-agglutination is largely a specific phenomenon, both in normal and pathological blood, and the specific effect can be shown to persist even if the red cells have been subjected to high degrees of temperature or to complete drying. (4) Hæm-agglutination and bacterial agglutination are distinct phenomena. (5) Well-marked isohæmolysis in specimens of normal and pathological blood is not common, although some degree of hæmolysis can frequently be demonstrated. (6) Concerning phagocytosis: It would appear necessary to avoid mixing specimens of normal or pathological blood, because just as samples of sera are known to vary in value, so do the leucocytes, although to a less extent, whether they are obtained from specimens of normal or pathological blood. Still further, by mixing samples of normal or pathological blood a hæmolytic action may be induced which in itself has been found capable of exciting abnormal results in phagocytosis. (7) It appears to be incorrect to regard a specimen of blood as normal until it has been subjected to a detailed examination by the methods referred to in this and the two previous communications, quite irrespective of its actual source.—L. **Doncaster**: Gametogenesis of the gallfly *Neuroterus lenticularis* (*Spathegaster baccarum*), part i. The cynipid *Neuroterus lenticularis* has two generations in the year, hatching in April and June. The April generation consists of females only, which lay parthenogenetic eggs. Evidence is given that some of these flies lay only eggs destined to become males, other flies only eggs which become females. The June generation thus consists of males and females; the eggs are fertilised and give rise to the generation which appears in April. In the spermatogenesis 10 chromosomes are found in the spermatogonial mitoses. In the spermatocytes, the first maturation division is abortive, only a small piece of cytoplasm with the centrosome being separated. In the second spermatocyte division 10 chromosomes appear and divide equally into the spermatids. The two spermatids are similar, except that one receives a small extra-nuclear body absent in the other. Somatic mitoses in the male show 20 chromosomes, except in the nerve-cells, which appear to contain 10 only. The eggs of the June generation undergo a double but irregular maturation division, apparently leaving 10 chromosomes in the pronucleus. Segmentation divisions in these eggs and body-cells in females of both generations show 20 chromosomes. The study of the maturation of the eggs of the spring (parthenogenetic) generation is not yet complete, but suggests that the eggs of some females undergo maturation and chromosome-reduction; those of others undergo no reduction. It is suggested that the former eggs yield males, the latter females. These observations, combined with (1) those of the author on the relation between sex and a somatic character in the moth Abraxas, (2) with the inheritance of such cases as colour-blindness, and (3) with the sex-relations of "heterochromosomes" in insects, lead to a hypothesis as to the nature of sex. It is suggested that there are male and female sex-determinants (symbols ♂, ♀) which behave as Mendelian characters, each being allelomorphic with its absence (symbol ⊙). Females have constitution ♀ ♂, and produce ♀ eggs and ♂ eggs; males have constitution ♂ ⊙, and produce ♂ and ⊙ spermatozoa. ♀ eggs are fertilised by ♂ spermatozoa, yielding females; ♂ eggs by ⊙ spermatozoa, yielding males.—Dr. E. **Schuster**: Preliminary note upon the cell lamination of the cerebral cortex of echidna, with an enumeration of the fibres in the cranial nerves.—Dr. F. W. **Mott**, Dr. E. **Schuster**, and Prof. W. D. **Halliburton**: cortical lamination and localisation in the brain of the marmoset. This research is one which has been carried out on lines similar to that previously published by two of the authors in relation to the brain of the lemur. A series of sections of the cerebral cortex has been examined in order to map out the extent and boundaries of the types of cell lamination observed. It is now well known that these differences are correlated with differences in function, and this method of histological localisation of function (as it may be termed) has been controlled by the physiological method of stimulation.—R. H. **Whitehouse**: The caudal fin of fishes (preliminary paper). The paper communicated is a summary of a fuller work on the caudal fin of fishes in general, but principally the Teleostei. It aims at a revision of the definitions of terms in general use, in order to disperse the vagueness surrounding these terms. Diphycercy is shown to be very vague, inasmuch as it does not specify the primary or secondary nature of the symmetry, and thus it may be dispensed with in favour of protocercy and gephyrocercy, the former of which implies primary, and the latter secondary, symmetry. Concerning heterocercy, the essential features of this condition are considered to be (1) an enlarged lower lobe, and (2) the retention of individual centra, when formed, to the end of the axis. The term "hypural" is introduced into this form, since there is evidence of these structures being formed by the union of radials and hæmal arches. Under homocercy, three varieties of fin-structure are discussed for the purpose of showing (1) the breadth of the term, (2) features which determine the degree of specialisation, and (3) the taxonomic value of the caudal. Evidences of caudal abbreviation are reviewed, and a re-defining of the term "epural" is given, by which this structure is considered the dorsal homologue of the ventral hypural. The presence of radials dorsally and ventrally is directed attention to, and also the composite nature of hypurals and epurals. Finally, evidence is given in support of the theory that the permanent homocercal caudal is a shifted anal, and, moreover, support is forthcoming among the Elasmobranchs.—H. E. **Arbuckle**: Some experiments with the venom of *Causus rhombeatus*.—Dr. V. H. **Veley** and Dr. A. D. **Waller**: The comparative action of stovaine and cocaine as measured by their direct effects upon the contractivity of isolated muscle. As tested by an independent method, these two drugs are found to be of approximately equal physiological action in correspondence with their affinity values.—Sir David **Bruce**, Captains A. E. **Hamerton**, H. R. **Bateman**, and F. P. **Mackie**: *Glossina palpalis* as a carrier of *Trypanosoma vivax* in Uganda.—Prof. W. M. **Hicks**: A critical study of spectral series, part i., the alkalies, H and He.—G. W. C. **Kaye**: The distribution of the Röntgen rays from a focus bulb. A Röntgen bulb was constructed with an antikathode the inclination of which to the beam of kathode rays could be varied at will. The bulb as a whole was also capable of rotation, and thus by the use of a stationary ionisation chamber, intensity distribution curves could be obtained for the X-rays. The hardness and intensity of the Röntgen rays were found to be almost independent of the obliquity of the antikathode. Some possible improvements in the modern focus bulb are suggested in the paper.—R. D. **Kleeman**: The direction of motion of the electrons ejected by the α particle. When an α particle collides with a molecule, we should expect that the direction of motion of the ejected electron depends on that of the α particle. If the whole or a part of the energy of ionisations is derived from the α particle, the electron should have a component of motion in the same direction as the direction of motion of the α particle. Some experiments to test this showed that when α particles are shot through thin metal foil more electrons are given off from the side of the foil where the α particles emerge than where they enter. This shows that the motion of the liberated electrons is on the whole in the same direction as that of the ionising α particle.—F. **Soddy** and A. J. **Berry**: Conduction of heat through rarefied gases. By the aid of the calcium absorption process of producing high vacua, the conductivity of twelve gases for heat has been determined at pressures so low that the actual path of the molecule is comparable with its mean free path (*cf.* Sir W. Crookes, Proc. Roy. Soc., 1880, 31, 239). By an electrical method the heat dissipated from a platinum strip, maintained at 61° in the gas, has been measured at various pressures down to a thermally perfect vacuum. As indicated by the kinetic theory, the heat dissipated at low pressure is proportional to the pressure, whereas at higher pressures it is independent of pressure. It was found that the conductivity in the first case bore no relation to that in the second. At all ordinary pressures hydrogen and helium are easily the best conductors, while of the gases examined carbon dioxide was the worst. At low pressure the conductivity of acetylene, methane, and cyanogen somewhat exceeded that of hydrogen, while helium was but slightly better than carbon dioxide. At low pressures the conductivity will be defined in terms of the calories ($x\ 10^{-5}$) dissipated per second, per 0·01 mm. of pressure, per sq. cm. of surface, per 1° difference of temperature between the surface and the wall of the containing vessel. The symbols K and Q will be used to express respectively the experimental and calculated values of the conductivity so defined. On the assumption that the heat interchange between the molecule and the surface it impinges upon is perfect, Q is the product of the number of impacts of the molecules per second per sq. cm. and the specific heat of the molecule. By the aid of the kinetic theory, Q may readily be approximately calculated from the mean molecular velocity and the molecular heat at constant volume. In the table the gases have been arranged in ascending order of K. In the second column, which gives the relative conductivity of the gas at ordinary pressures, the figures refer to the watts dissipated by the gas in the apparatus at pressures such that conductivity was independent of pressure. In the last three columns the values of K, Q, and of the ratio of K to Q, are given.

	Watts.	K.	Q.	K/Q.
Argon	1·07	1·30	1·20	1·09
Neon	2·35	1·76	1·70	1·04
Carbon dioxide ...	0·95	1·89	2·64	0·72
Oxygen	1·55	1·91	2·23	0·86
Helium	7·30	1·94	3·80	0·51
Carbon monoxide ...	1·37	1·96	2·38	0·82
Nitrous oxide ...	0·97	2·11	2·75	0·77
Nitrogen	1·44	2·21	2·35	0·94
Hydrogen	8·75	2·29	8·95	0·25
Cyanogen	0·97	2·35	—	—
Methane	2·81	2·70	3·95	0·68
Acetylene	1·24	2·75	3·82	0·72

For argon and neon the agreement between the observed and calculated conductivity is as good as can be expected, whereas for all the other gases the ratio is less than unity, and in the case of hydrogen and helium the divergence is especially marked. The results appear to afford the means of obtaining information concerning the nature of the single impact of the gas molecule with a surface. Whereas for the denser monatomic gases the interchange of energy appears perfect, for the more rapidly moving molecules of helium and hydrogen this is not the case. The results are preliminary, and the conclusions now tentatively suggested are being tested further with improved apparatus.—T. **Wright**: Harmonic tidal constants for certain Chinese and New Zealand ports.—S. **Kinoshita**: The photographic action of the α particles emitted from radio-active substances. The photographic action of α rays is quite distinct from that of light. There is no diminution in the action when the rays are screened by an absorbing substance, so long as they are capable of passing through the photographic film. In the case of light, the action varies with the intensity of the light, which decreases on passage through an absorbing screen. The photographic action of α rays is thus independent of the velocity of the rays and depends on the number of α particles, N, which passes through the film and can be expressed, when measured by the density, D, as

$$D = D_{max}\left(1 - e^{-CN}\right), \text{ where C is a constant.}$$

This formula can be theoretically deduced on the assumption that each halide grain is rendered capable of development when struck by a certain number of α particles. By counting the number of silver grains in the film exposed to a known number of α particles, it was found that each halide grain was rendered capable of development when struck by a single α particle. The mass of silver per unit area of a developed film, calculated from the number of grains and their average size (deduced from the constant, C, in the above equation) by a consideration of the theory of probability, agrees well with the value determined from the density and the photometric constant. The sensitiveness of a photographic film to α rays cannot be characterised by its inertia. A rapid plate is more sensitive to α rays than a slow plate, if density be taken as a criterion. The reverse holds, however, when the number of grains is considered, provided that the total amount of silver halide per unit area is the same in both cases. The authors have now this new method of counting single α particles, in addition to the electrical and scintillation methods. The photographic method should prove very valuable for counting very small numbers of α particles, since it is applicable to very weak sources by using very long exposures, and also to α particles having a very short range.—Hon. R. J. **Strutt**: The accumulation of helium in geological time, III. The present experiments refer to the amount of helium in zircon. This mineral is found in igneous rocks of all ages, and the experiments show clearly that the quantity of helium generated closely follows the geological age. This must not be taken to prove that they retain the whole of the helium generated within them by radio-active change, but rather that, as they all crystallise from fusion, they are all of similar structure, and retain a not very different fraction of the full quantity of gas in each case. The following table summarises the results. The last column shows the ratio of helium to radio-active matter (c.c. per gram of uranium oxide), thoria being reckoned as equivalent, in helium production, to 0·203 times its weight of U_3O_8:—

Locality.	Geological Age.	Per Gram of Zircon.			Helium Ratio
		Helium cc. × 10^{-4}	U_3O_8 Grams × 10^{-8}.	ThO_2 Grams × 10^{-4}.

Royal Anthropological Institute, December 14.—Mr. H. Balfour, past-president, in the chair.—E. **Torday**: Results of a recent ethnographical expedition to the Congo Free State. The expedition left England in October, 1907, and travelled by the Kasai and the Sankuru to the Ba-Songe country. The Ba-Songe are a tribe of the Ba-Luba people, whose affinities lie rather to the south. The next tribe visited was the Ba-Tetela, a cannibal people who occupy a large extent of country between the second and fifth degrees of southern latitude. These people seem to have been extending, gradually but steadily, south and west from the Lower Lomami. Their culture is interesting as exhibiting a transition between that of the forest and of the plains. Other tribes visited were the Bu-Shongo, the Akela, and the cannibal Ba-Nkutu, who seem to have cultural affinities with the northern Ba-Tetela. The Ba-Songo Meno, a term given to a large number of tribes on both banks of the Kasai between the Sankuru and the Mfini, were also visited. These tribes have never been investigated, and show great hostility to the white man. The western Bu-Shongo tribes were also visited. These people, originally migrants from the north, gained most of their culture from the tribes to the west, and it was with these people that the paper chiefly dealt, including the Ba-Kongo and the Bashi Lele, who represent the first waves of Bu-Shongo immigration into the country. With regard to history, it is a remarkable fact that the Bu-Shongo people have preserved their records. The name means people of the Shongo, the shongo being a weapon, now obsolete, which was the principal arm of offence in the early days. The chief drew a picture of this weapon in the sand, and it was unmistakably a throwing knife. Now the throwing knife as a weapon does not occur south of the great bend of the Congo. The argument, therefore, that the people originally came from the north is strengthened by this fact, as the north was the original home of the weapon. From evidence of language, tribal history, and culture, the original home of the people seems to have been the west central Sudan. The remainder of the paper dealt with the institutions, government, and religion of the people. The tribal organisation is extremely elaborate. At the head is the chief, but in certain points his mother appears to take precedence. There are also six great officers and a host of other officials. Although nominally absolute, the chief has little real power. The right to the throne descends in the female line, but a woman can only come to the throne if the male stock fails.

This is the theory. In practice the chief has the power practically of nominating his successor, as he can disinherit any likely claimant. In religion the Bu-Shongo believe in an all-powerful creator, but they pay no worship to him. Magic is largely practised. The spiritual nature of man is considered to consist of three elements, soul, double, and shadow. The soul only leaves the body at death, the double at both death and sleep, and the shadow only at death, the belief that a corpse cannot cast a shadow being current among the people. The nearest approach to true totemism as yet discovered in Africa was found among the western Bu-Shongo, where each person inherits from his father an Ikina, a plant or animal which he may not eat. This Ikina has no connection with tribal names, and the division into Ikina cuts across the division into tribes and villages. Persons possessing the same Ikina may not marry.

Royal Meteorological Society, December 15.—Mr. H. Mellish, president, in the chair.—Dr. W. N. **Shaw**, F.R.S.: The variations of currents of air indicated by simultaneous records of the direction and velocity of the wind. In order to form a mental picture of the changes which are taking place in the amount of air flowing past an anemometer, we need to take into account the changes of direction as well as the changes in velocity. The author had endeavoured to combine these in what he called a "vector diagram," and he pointed out some interesting results which he had obtained from such diagrams.—W. G. **Reed**, jun.: A critical examination of South American rainfall types. The object was to make a simple yet accurate map showing the seasonal distribution of rainfall in South America.—W. G. **Reed**, jun.: The study of phenomenal climatology. The suggestion has several times been made that treatment of weather elements by days and months is arbitrary and unnatural for places not within the tropics. The author points out that in latitudes subject to cyclones the distribution of weather elements depends largely upon the relation of cyclones and anticyclones, and he therefore suggests that the cyclone is a more rational unit than the day or the month.

Edinburgh.

Royal Society, December 6.—Prof. Cossar Ewart, F.R.S., vice-president, in the chair.—Dr. D. C. L. **Fitzwilliams**: The short muscles of the hand of the agile gibbon (*Hylobates agilis*), with comments on the morphological position and function of the short muscles of the hand of man. The material was supplied by the late Prof. Cunningham. The extraordinary length of the upper limb of the agile gibbon, and the manner in which it uses the hook-like hand as it swings itself from tree to tree, have an influence upon the anatomy which can be clearly recognised, especially in regard to the muscles. Thus in the gibbon the muscles of the hand tend to wander down the phalanges. This is evidently a mechanical gain, and is a response to the demands of function. The paper contained an elaborate comparison of the layers of muscles in the hand of the gibbon with the arrangements in the human hand, the discussion being based upon the distribution of the three primitive layers which, according to Cunningham, characterise the typical mammalian manus.—G. **Green**: Waves in a dispersive medium resulting from a limited initial disturbance. Following up a former paper on group velocity, the author investigates the effect of the same initial disturbance in all media in which the velocity of an infinite train of regular waves is proportional to the wave-length. The results obtained are similar to those given by Prof. Burnside for water waves in his paper on deep-water waves resulting from a limited original disturbance, of which the paper is an extension. It is shown that in all the media considered the greatest disturbance at each point is inversely as the square root of the distance of the point from the place of the original disturbance, and the wave-length of the disturbance when greatest is the same for every point, being determined entirely by the form of the initial disturbance.—Dr. W. A. **Caspari**: The composition and character of oceanic Red Clay. The chemistry of this deposit, though it has received attention from several investigators, still presents uncertainties. At Sir John Murray's suggestion a re-investigation of the whole subject from the chemical standpoint was undertaken. Moreover, Sir John Murray's unique collection of deep-sea deposits afforded the opportunity of choosing a highly representative series of red clays from all parts of the world. The methods and the results of analysis are given in detail. Regarding the general question of the molecular constitution of submarine clays, the author concludes that these hydrous silicates are not so much definite chemical compounds or mixtures of such as agglutinates of colloidal silica, alumina, &c., in inconstant proportions. What the affinity is which binds the constituents together we do not know, but it is certainly not exclusively chemical. In the Red Clay areas we have a temperature of 1° C. to 3° C., pressures of 400 to 600 atmospheres, and a uniform medium (sea-water), conditions which give to deep-sea weathering features which sharply contrast with subaërial weathering. The degradation product has much the same composition all over the globe, and it is a more acid silicate than the corresponding continental material. Clearly silica can escape into the hydrosphere just as well as alkalies and alkaline earths. On the whole, there seems to be something approximating to a genuine equilibrium between Red Clay and sea-water. When the colloidal nature of Red Clay is realised, the invariable presence of calcium, magnesium, and alkalies causes no surprise. This retention of highly soluble matter may be ascribed to capillary action at the enormous surfaces presented by the fine grains of clay and their internal framework, but the possibility that chemical affinities are also exerted is not to be disregarded. Potassium, calcium, magnesium, and sodium are withdrawn, in approximately constant proportions, out of the sea-water. The order given is the order of their adsorbability, and is just the reverse of their abundance in sea-water.

Paris.

Academy of Sciences, December 13.—M. Bouchard in the chair.—H. **Deslandres**: Arrangement of the large telescope at Meudon for the photography of comets. Application to the Halley comet. Details are given of the addition of a finder to the large telescope and its mode of use for keeping the image of the comet on a fixed point of the photographic plate.—H. **Deslandres** and A. **Bernard**: Preliminary note on the spectrum of the Halley comet. At the Lick Observatory W. Wright found this comet to give an absolutely continuous spectrum; the results obtained by the authors, on the contrary, show clear discontinuities in the spectrum. There is a possibility that two condensations noted in the ultra-violet are near the bands λ 388 and λ 391·45 found in the Morehouse comet. Further measurements are required, but it seems proved that the comet shines by its own light, part of which is due to incandescent gases.—H. **Poincaré**: A generalisation of the method of Jacobi.—M. **Coggia**: Observations of comets made at the Observatory of Marseilles with the Eichens 26-cm. equatorial. Data are given for Daniel's comet on December 9 and 10, and Halley's comet on December 2, 3, 4, 5, 8, 9, and 10.—Eugène **Bloch**: The Hertz photoelectric effect. The classification of metals in the order of their photoelectric effect is modified by the wave-length of the light employed.—G. A. **Hemsalech** and C. **de Watteville**: The line spectrum of calcium given by the oxy-acetylene blow-pipe. The spectrum approaches that of the arc in the number and intensity of the lines. The relation between the number of lines and the nature of the flame is discussed.—A. **Lafay**: An arrangement for the determination of very small differences of pressure. A silvered collodion film is displaced by the pressure to be measured and brought back to its original position electrostatically, an interference method being used to measure the displacement.—E. **Caudrelier**: The discharge of inductors. The influence of the primary condenser on the length of the spark.—Louis **Dunoyer**: The variation in the conductivity of glass with temperature.—P. A. **Guye** and N. **Zachariadès**: The reduction of weighings to a vacuum applied to the determination of atomic weights. A revision of the figures given in an earlier paper, in which the errors caused by the presence of occluded air in the salts weighed are determined. This occlusion of air results in the density assumed in the corrections to the weight in a vacuum being taken too low.—L. **Bruninghaus**: A relation between absorption and phosphorescence.—J. **Taffanel**: Experiments relating to the propagation of coal-dust explosions in mine workings. The inflammation of the coal-dust was started in these experiments either by exploding a small charge of dynamite or some cubic metres of a mixture of methane and air. Measurements of the velocity of propagation of the wave at varying distances from the firing point were made, and the effect of obstructions and changes in the direction of the gallery studied.—E. **Goutal**: The estimation of carbon monoxide in steel. In a previous paper the author has shown that during the solution of iron or steel in cupric chloride a small amount of carbon monoxide is given off, corresponding to about 0·006 per cent. of the carbon in the steel. The first experiments were carried out with iodine pentoxide as the oxidising agent; it is now shown that identical results are obtained when blood is used as the reagent. An amount of carbon monoxide of 0·0142 per cent. by weight represents the limit of saturation for solid steel.—Emm. **Pozzi-Escot**: The separation of vanadium, molybdenum, chromium, and nickel in special steels.—G. **Chesneau**: The analysis of niobites and tantalites. The proposed process is described in detail, and as an example of its application the complete analysis of a tantalite is given.—P. **Freundler**: Some *c*-oxyindazylic derivatives.—Marcel **Godchot**: Some derivatives of dicyclohexylphenylmethane.—M. **Chevalier**: The scientific expedition to eastern Africa, September and October, 1909.—L. **Trabut**: Some facts relating to the hybridation of Citrus and on the origin of *Citrus aurantium*.—E. **Coquidé**: The plurality of the types of vegetation in the peaty soils of the north of France.—A. **Prunet**: The resistance of the Japanese chestnut to disease (*maladie de l'encre*). The chestnut has been destroyed in various parts by a cryptogamic disease of the roots, and experiments have been made during the last six years on the possibility of replacing the French trees by an American or Japanese variety. The American tree did not resist the disease, but so far the Japanese tree appears to be immune. The latter grows well, and its introduction may have important economic consequences.—Paul **Becquerel**: The variations of *Zinnia elegans* under the action of traumatisms.—Émile **Gautrelet**: The partial transformation of fatty food materials by pepsic and pancreatic digestion *in vitro*. It is shown that mannites are the result of this partial digestion.—H. **Guillemard**, R. **Moog**, and G. **Regnier**: The dehydration of the organism by the pulmonary and cutaneous channels and its variation with altitude.—Maurice **Holderer**: The influence of the reaction of the medium on the filtration of the diastases. Sucrase from *Aspergillus niger* was chosen as the diastase for these experiments. In media neutral to phenolphthalein, this sucrase passes entirely through porcelain filters; in media neutral to methyl orange, the sucrase is completely retained by the filter.—R. **Anthony**: The elevation of *Zeugopterus punctatus* at the maritime laboratory of Saint-Vaast-la-Hougue.—L. **de Launay**: The characteristic features of hydrothermal springs.—Paul **Lemoine**: The magnitude of the shrinking produced by the folds of the Paris basin.—G. **Delépine**: The succession of fauna and the distribution of the facies of the Carboniferous limestone of Belgium.—René **Gambier** and Armand **Renier**: Observations on Pinakodendron.—E. A. **Martel**: The subterranean hydrology of the *massif* of Penè-Blanque or Arbas, Haute-Garonne.—Charles **Moureu** and A. **Lepape**: The gases from thermal springs: the presence of krypton and xenon. The gases from twenty-six springs were freed from gases other than the rare gases in the usual way. The residual rare gases were fractionated, firstly, by wood charcoal at the temperature of liquid air, thus separating the helium and neon, and the remainder further treated with charcoal at −23° C. The xenon and krypton were then obtained from the charcoal. These two gases were identified in every one of the waters examined. Blank experiments were also carried out to guard against the possibility of a leakage of air into the apparatus during the analyses, with negative results.

CALCUTTA.

Asiatic Society of Bengal, December 1.—W. A. **Inglis**: Rivers of Bengal. The author refers to Captain Hirst's article on the Kosi River, and discusses the general question of the construction of marginal embankments, which have for their object the prevention of the overflow of floods.—D. **Hooper**: The secretion of *Phromnia marginella*. In north-east India the larvæ of these insects secrete in the dry weather a saccharine substance, which gives to the plants they affect a snow-white appearance. The chief constituent of this deposit is dulcitol (dulcite). The Phromnias are frequently found upon Celastrus, Elæodenoton, and other species of Celastrinea, and it is interesting to know that chemists have isolated dulcitol from several plants of this natural order.—Hem Chandra **Das-Gupta**: A probable identity between *Clypeaster complanatus*, Duncan and Sladen, and *Clypeaster Duncanensis*, Noetling. The author gives reasons for thinking that *Clypeaster Duncanensis*, Noetl., was founded on large specimens of *Clypeaster complanatus*, Duncan and Sladen.

BLOOD-SUCKING FLIES.

Illustrations of African Blood-sucking Flies, other than Mosquitoes and Tsetse-flies. By E. E. Austen. With coloured figures by Grace Edwards. Pp. xv + 221; 13 plates; 3 text-figures. (London: British Museum, Natural History, 1909.) Price *1l. 7s. 6d.*

THE extraordinary progress that has been made of recent years in the study of tropical medicine has had the result of establishing clearly the general truth that most of the diseases peculiar to the tropics, whether of man or animals, are due to the effects of parasites, microscopic or ultra-microscopic, introduced into the system by the agency of blood-sucking invertebrates. The intermediate host in such cases is usually an arthropod, and most frequently a dipterous insect. Not only has this mode of infection been demonstrated beyond all possibility of reasonable doubt, for such formidable scourges as malaria, yellow fever, sleeping sickness, and various diseases caused by trypanosomes in animals, such as nagana and surra, but it is highly probable that many other forms of disease, less thoroughly investigated at present, originate in a similar manner. Moreover, as in many other cases of parasitism throughout the animal kingdom, a particular disease-producing parasite may be transmitted from one vertebrate host to another only by one restricted group, perhaps even by a single species, of the blood-sucking invertebrates concerned, while other forms may be incapable of harbouring the parasite, or, to express the matter more correctly, are capable of digesting the parasite together with the blood, when taken up in the usual course of feeding.

For these reasons the study of the Diptera, or two-winged flies, has assumed an importance which, twenty years ago, could hardly have been foreseen either by the scientific or the practical man, even in the wildest flights of the imagination. At that epoch, which seems very remote when considered from the standpoint of present knowledge, none but professed entomologists, and not many even of them, occupied themselves with a group of insects unattractive or even repulsive when compared with such popular favourites as butterflies or beetles. Now, however, the Diptera and other blood-sucking arthropods are studied eagerly in all parts of the world, and not by specialists alone. The scientific knowledge of these creatures, their habits and life-histories, has become of immense importance from the economic and medical standpoint, and the distinction and recognition of forms harmful or harmless, from the human point of view, is a branch of study which has invaded even the medical curriculum, at least in schools of tropical medicine. The attention of the medical man is not directed solely, however, to blood-sucking insects, since it is becoming generally recognised that the common flies which haunt our houses and crawl over our food are also fruitful sources of disease.

An Englishman may feel legitimate pride in the lead taken by our national museum in this branch of study. Under the auspices of the British Museum of Natural History, and by the initiative and encouragement of its former director, Sir Ray Lankester, a number of works on blood-sucking Diptera have been published, works of the highest value both from the scientific and the practical point of view. The museum is especially fortunate in having the services of the foremost authority on the Diptera, Mr. E. E. Austen, whose monograph on the tsetse-flies is now a classic, and recognised all over the world as the standard work on these insects.

In the present work Mr. Austen excludes the tsetse-flies already dealt with by him, and the mosquitoes, on which a monograph by Theobald is in progress, and deals with other African blood-sucking flies. He aims at giving descriptions, figures, and general information such as will enable, not only experts, but more especially travellers and medical men in Africa to distinguish and identify the various forms already known, and to collect more material for the study of the Diptera, and so fill some of the many gaps in our knowledge of this group. It is not possible to praise the work more highly than by saying that it comes up to the standard of former works by the same author. Written with a view to the requirements of those who are not specialists, the book does not contain cumbrous descriptions in technical language, but relies chiefly on the excellent illustrations. Every species of fly dealt with is figured in colours at a scale of magnification indicated by a line below the figure. The distinctive characters of the families and genera are given in plain language, together with brief accounts of their habits, life-histories, and relations to disease, so far as such facts are known at the present time. The species are not described in detail, but where necessary their distinctive features are pointed out, and their distribution is given, with a list of the localities whence the specimens in the museum have been obtained. Finally, a list of the flies is given, arranged under countries, so that anyone residing in Africa or intending to travel there can see at once what biting flies other than tsetses or mosquitoes are known at present to occur in any particular region.

This book fulfils admirably the purpose for which it is intended, and will certainly be of the utmost value to travellers and residents in Africa. It will also stimulate the collection and study of these insect-plagues, and will thereby contribute more than any other cause to itself becoming out of date. It is to be hoped that supplementary volumes will be published as material accumulates and knowledge increases. If so, the supplements will probably far exceed in bulk the original work, in course of time. The subject-matter of the work could only be criticised by an expert, and is distinguished by erudition and accuracy. The arrangement of the contents is clear and time-saving, with a complete index. The illustrations are admirably executed and reproduced. If we might offer a suggestion, it is that a national achievement of such importance would have its value and usefulness greatly increased if its price were more within the reach of modest means. Doubtless such a book is very expensive to produce, but surely this is a case where the wealthy treasury of a great nation might have balanced a possible pecuniary loss against a certain imperial gain.

E. A. M.

A NEW TEXT-BOOK OF PALÆOZOOLOGY.

Lehrbuch der Paläozoologie. By Prof. E. Stromer von Reichenbach. I., Wirbellose Tiere. Pp. x+342. Naturwissenschaft und Technik in Lehre und Forschung. (Leipzig: B. G. Teubner, 1909.) Price 10 marks.

IN several features the present volume may well claim to be in advance of many of the text-books on the subject which have appeared during latter years. Instead of being a mere systematically arranged and uninteresting descriptive catalogue, it provides splendid material for the student who desires an intelligent understanding of the subject.

In a well-written introduction the author discusses the scope of the science, the history of its origin, the present state of our knowledge of the science, conditions of fossil-preservation, the relationship of palæozoology to other sciences, and, lastly, the constitution of the skeleton in different animals. For the most part the work is limited, except in some of the more thoroughly investigated groups, to the treatment of orders and higher divisions. Greater detail would have defeated the end in view—that of providing a clearly written exposition for beginners who are assumed to have only elementary knowledge of zoology and no acquaintance with geology. The lower animals receive much attention, and their discussion occupies a considerable portion of the volume. An attempt has been made to embody the recent researches in the different sections without unduly obscuring the clearness. Thus, for instance, in the section on the rugose corals is given the explanation of the septal plan as recently set forth by Carruthers.

Other important features are the paragraphs on the geological distribution and the evolution of each group, as well as the concise summary of the diagnostic characters of the several groups at the close of the treatment of each phylum. A general discussion of the contributions of palæozoology to the study of phylogeny is reserved for the second volume. A valuable list of the chief works at the end of each section provides the necessary guide to those students who might wish to continue the subject further.

The use of a special mark to signify extinct forms is unfortunate, since the necessary frequence of these signs in some parts proves to be a distracting eyesore. Moreover, Frech has used the same mark in his "Lethæa Palæozoica" to denote the last appearance of a form in the stratigraphical sequence.

Undoubtedly, one of the outstanding features of the book is the excellence of the illustrations and the introduction of so many that are new in a text-book. The clearness of the figures and the conciseness of the explanatory notes leave nothing to be desired. The inclusion of technical terms such as "latisellat," "kryptodont," and "iterative Formenbildung," in the index must prove very useful.

On the whole, the author can be congratulated upon producing a very good and serviceable text-book, for he has succeeded very well in preserving the educationist's ideal of a treatment proceeding "from the known to the unknown," and not, as is often the case, "to the unknown through the more unknown."

IVOR THOMAS.

CHEMISTRY IN COURT.

A Manual of Forensic Chemistry, dealing especially with Chemical Evidence: its Preparation and Adduction. Based upon a Course of Lectures delivered at University College. By William Jago. Pp. viii+256. (London: Stevens and Haynes, 1909.) Price 5*s.* net.

IN one way or another, chemical matters form no insignificant proportion of the cases dealt with by our police courts and civil tribunals. Poisoning tragedies, infringement of patents, adulteration of food, and even libel actions—these are some, but by no means all, of the causes which serve to bring chemist and lawyer professionally together; and, not infrequently, chemist and lawyer find themselves at loggerheads.

There are legal subtleties which the chemist is apt to overlook. For example, a well-known scientific witness once set out to explain what a certain claim in a specification meant. "Kekewich, J.," interposed with the remark, "That is for me, Sir James." So the witness had to cast about for a more acceptable form of words. "Speaking as a chemist," he said, "the following words in the claim mean to me" so and so. With this preliminary the evidence was admissible, and the witness was allowed to proceed.

On the other hand, there are chemical distinctions which to the lawyer are often a mystery of mysteries. Our author recognises this, and seeks, as far as may be, to make the rough places plain for the members of both professions.

For the lawyer, he explains shortly the objects and principles of chemistry. He gives examples of "direct" and "indirect" methods of analysis, and directs attention to such points as the collection of fair samples, the changes which in perishable articles may affect the analysis, the occurrence of "traces" of a constituent, and the control of results by "blank" experiments. For the chemist, there is very good advice on such matters as the preparation of the "proof," the form of the certificate, and the use of books in the witness-box. For both, there is a collection of illustrative cases, bringing out the chief points and rulings which affect present-day practice. Many of the *causes célèbres* of the last fifty years are quoted. Thus the Palmer and the Maybrick poisoning prosecutions, the cordite litigation, the "what is whiskey?" proceedings, the libel action in connection with altar candles, and the disputed validity of the Badische Anilin Company's patents, are some of the many cases which are made to point a moral for the reader's benefit.

Possibly a little more chemistry would have been welcome to the lawyer. Perhaps, also, the chemist would like to see a fuller discussion of the principles of evidence after the manner adopted on p. 245, where not only the practice but the reasons for it are adduced. Precedents, however, bulk largely in legal work; and if the chemist, from his training and mental leanings, would rather have had more principle and less precedent, it does not follow that he would have found it of more actual utility. Nevertheless, the author might note these suggestions in view of a second edition. In any case, the book can be recommended as a helpful and interesting one to those for whom it is written. C. Simmonds.

THE MORPHIA HABIT.

The Morphia Habit and its Voluntary Renunciation. A Personal Relation of a Suppression after Twenty-five Years' Addiction. By Dr. Oscar Jennings. Pp. x+492. (London: Baillière, Tindall and Cox, 1909.) Price 7*s*. 6*d*. net.

It were well, if time permitted, that each physician should experience in his own person (meaning thereby his whole person, psyche and soma) a few typical examples of the complaints which he will have to treat. He would thus acquire an insight into disease obtainable in no other way, and with Æneas might exclaim:—

> "Quæque ipse miserrima vidi,
> Et quorum pars magna fui."

This apt quotation is found on the title-page of Dr. Jennings's book, and its aptness lies precisely in this, that the book includes, in the shape of a diary, the record, from within, of the overcoming of an addiction to morphia of twenty-five years' standing. Of habit, pernicious, no more typical example could have been selected than the morphia habit, and this treatise presents us with a valuable contribution to the study and solution of a very serious problem.

Dr. Jennings approaches the problem by two paths, the psychologic and the somatic, in this order. His primary demand is that the patient shall bring, on his part, the desire, the intention, the will (what remains of it), to get well; that before all else the psyche point in the right direction. His next demand is that the physician shall, on his part, supply encouragement, and shall instil into the patient, first a full confidence in himself as guide, and then a spirit of self-reliance; or the order may be reversed, it does not matter so long as hope, trust, and self-reliance find an entry. He urges, and it must be clear, that the best of all cures can only be upon these lines, and that cures which have been effected without the patient's willing cooperation, *a fortiori*, against his will, must be inferior in value. To seek a simile, the willing and the unwilling cure may be likened to the cure of an infectious disease, brought about, on the one hand, by the successful resistance of the patient's own tissues, on the other, by the aid of antidotal powers (anti-toxins) which the efforts of alien tissues have supplied. We have reason to believe that the immunity acquired by the former is the more complete and the more lasting.

Dr. Jennings, however, is not content with teaching a reasonable doctrine; he shows further, by his record of successful cases, the feasibility of the plan which he advocates. With much practical wisdom, he will not allow us to forget that the problem has a somatic side; he is too good a physiologist not to see that to deny this is to deny physiology, "the solid ground of nature"; also that to recognise a somatic side, yet to deny the possibility of material access to the body, as by the medicaments, is to deny physiology once again, since pharmacology is but a department of physiology. On this subject, the value of drugs in the treatment of the morphia habit, the author has much of interest to tell; in particular he insists upon "his therapeutic triad," the use, namely, of heart tonics—of alkalies, especially Vichy water—and of hydropathic measures, notably the Turkish bath. His views do not always fit in with pharmacological teaching, *e.g.* in the value which he assigns to sparteine, but here the last word must rest with the clinicist.

Dr. Jennings's dietetic handling of his subject strikes the reviewer as interesting and original, and as mindful of the dietetic wisdom of the Hippocratic aphorisms.

By means dietetic and medicinal, as set forth by the author, the stress of the bodily cravings is eased and the enfeebled will enabled to maintain its operation; maintaining its operation, volition, according to the law of growth, is gradually built up, the habit of right operation becoming ingrained. Thus in the re-education of the will, the great force of custom is called upon to help to overthrow that dominance which the great force of custom had established—"Certa viriliter"; said S. Thomas à Kempis, "consuetudo consuetudine vincitur." The victim of habit may take these words to heart, and in this record of Dr. Jennings find further encouragement to persevere, and along what lines to seek and find health.

SCHOOL GARDENS.

Practical School Gardening. By P. Elford and Samuel Heaton. Pp. 224. (Oxford: Clarendon Press, 1909.) Price 2*s*. net.

Few educational movements of recent years have produced a more copious crop of text-books, hand-books, readers, and so on, than what is called nature-study. This result is not quite in harmony with the spirit of the movement, which is to avoid the book and study the thing. The child is to use his own eyes, to observe the thing itself in its proper habitat, and in relation to its ordinary surroundings; from these observations he is to make deductions, and thus he is to be trained to think. Of course, the scheme has to be modified to suit the exigencies of the time-table, but it has been shown to work and to give country children a living interest in their surroundings, besides providing the teacher with a powerful engine for education. The final success of the method depends, however, on how far the teacher himself possesses the proper habit of mind, and how far he has overcome the dependence on text-books which has been fostered by his training and the habit, born of tradition and the old method of education, of looking a thing up in a book rather than discovering it by observation. One of the consequences of the movement, and one which we hope will prove permanent, has been the establishment of school gardens. Anyone who knows village schools where gardens exist knows the pride that teachers and scholars alike take in them, and their great value from every point of view. A school garden can be made to furnish a vast amount of matter for school lessons, and in addition it instils into the boys that love of gardening so characteristic of the English life of to-day.

The teacher is bound to have text-book help in managing his garden; the proper arrangement of his crops, the times of sowing, the pests or diseases likely to be troublesome, are all matters in which he needs guidance. He cannot afford to make mistakes, his scholars' parents are sometimes expert gardeners, always critical, and ever ready to derive amusement from his little efforts. The book before us will be found very useful in this respect by the teacher, and the instructions for working are quite clear and have been tested with satisfactory results in the school gardens of Oxfordshire. The book is copiously illustrated; indeed, we find a whole page devoted to the photograph of a wheelbarrow and an ordinary watering can. The teacher who intelligently follows the instruction given may quite expect his garden to be successful from a horticultural point of view, and will have little to fear from the carping village critics.

But we do not think this book represents the last word on the subject. Not enough is made of the garden as a means of education, in spite of a highly suggestive chapter by Mr. Meadon on "Discovery Lessons," which shows a full appreciation of the possibilities in this direction. We should like to have seen the book dominated by the spirit of the *experimenter*; instead, we find it dominated by the spirit of the horticultural *instructor,* whose personality comes out on every page, even to the amiable weakness for the long Latin name that we ever associate with the professed horticulturist. It must be admitted, however, that there are difficulties in the way of an experimental school garden. A garden often becomes much too personal an affair to be made the subject of experiment even by the man of science, and how shall the village schoolmaster treat it any more impersonally? The spirit of competition is there; each boy wishes his plot to be the best, and the teacher wishes the garden as a whole to be at least as good as the allotments; experiments, therefore, cannot come in, as he has no room for failures. We are aware, of course, that some schools make trials with artificial manures, but the schemes that we have seen have been entirely empirical, and designed to increase the crop rather than to yield information. We believe that ultimately the school garden will be as successful educationally as it now is horticulturally, and although the present book does little towards helping on this reform it will be found of real value for the school garden as at present conducted. E. J. RUSSELL.

ELECTRIC MOTORS.

The Alternating Current Commutator Motor and the Leakage of Induction Motors. By Dr. Rudolf Goldschmidt. Pp. viii+210. (London: The *Electrician* Printing and Publishing Co., Ltd., 1909.) Price 6*s*. 6*d*. net.

THOSE who are acquainted with Dr. Goldschmidt's writings will open this book with the expectation of finding a very intricate subject treated in clear and simple style, and this expectation will be fully realised. There is no padding, and consequently the reader must not skip, but if he follows the author conscientiously step by step in his close and methodical reasoning he will find his labour amply repaid.

A good deal has been written about the commutator motor, but we have never come across a treatise written so clearly and in such simple language. The simplicity of treatment is not attained by making inadmissible propositions. It is true the author takes us first through the theory of the so-called perfect motor, having no losses and no leakage, but after establishing the main principles which must count in any theory he goes on to introduce step by step those disturbing influences which are inseparable from the practically possible motor, and at every step he finds an easy way of taking account of these influences. The treatment is in the main graphical, and the author's position in the old controversy between the analytical and graphical school is shown by a passage on p. 30, which runs as follows:—

> "The preference for the mathematical or graphical representation is a matter of taste, but I think that many people will agree with me that a very simple diagram, as the present one, will lead more quickly to a clear result, and can more easily be borne in mind, than a more or less complicated formula."

The first part of the book, dealing with the commutator motor, contains six chapters—introductory, the series motor, the repulsion motor, the Latour-Winter-Eichberg motor, some special types, and finally examples of motors, with views and curves of performance, but not many technical data of construction. The only example illustrated by dimensioned working drawings is a 60-h.p. motor made by the Oerlikon Co. The brevity of style is certainly commendable, but in some places it is carried too far. Thus on p. 44, when dealing with the minimum flux required for sparkless commutation, the author gives without proof a formula in which the total flux, that is, the flux per pole multiplied by the number of pairs of poles, is shown to be proportional to the square root of a fraction containing in the nominator the product, horse-power, volts, and length of armature, and in the denominator the product revolutions per minute and diameter of armature. As he says that this formula "will do good service in formulating a general idea of the amount of flux required," we may fairly expect that he should give a proof of it. Another matter in which a somewhat fuller treatment might well be expected is the Deri (not Dery, as the author writes) motor. One page can hardly be considered sufficient to deal with a motor which presents so many interesting features, and is also, from a practical point of view, of immense importance. These are, however, minor blemishes of the author's work; the important thing is that he has given us an eminently useful and readable book on a subject which has too long been neglected in this country.

The second part of the volume under review deals in great detail with the leakage of induction motors and its predetermination. It is a careful investigation of all the different items which influence leakage, power factor, and overload capacity. The subject is highly technical, and will, therefore, mainly interest the designers of induction motors. Specialists in this branch will, however, find the author's method of dealing with the question of leakage, and especially his diagrams and tables, very useful.

GISBERT KAPP.

OUR BOOK SHELF.

Practical Microscopy. An Introduction to Microscopical Methods. By F. Shillington Scales. Second Edition. Pp. xvi+334. (London: Baillière, Tindall and Cox, 1909.) Price 5*s.* net.

ALTHOUGH nominally this is a second edition of Mr. Scales's "Elementary Microscopy," published in 1905, yet it is in effect a new book. The first edition was not so pretentious, and did not attempt to give so much information on widely varying branches of microscopy; in fact, if any criticism may be offered, it is that now too much is attempted.

The actual practical instruction in the use and manipulation of the microscope is particularly lucid, and it is difficult to imagine that it could be expressed more clearly. The theoretical side is practically untouched, perhaps wisely so, as to have gone into the theory with sufficient fulness to have made it intelligible to the ordinary reader would have entailed a great increase in the amount of matter.

The subject of photomicrography has been touched on, and this constitutes an entirely new chapter in the book, as in the first edition no attempt was made to deal with it at all. The instructions given are clear, but are in some respects not so full as an earnest student would desire.

The recently re-introduced methods of dark ground illumination are described, and practical instructions are given in the use of typical illuminators. The various methods of illumination of opaque objects are fully dealt with, both by means of an ordinary condensing lens used in conjunction with low powers and by vertical illuminators for use with high powers.

In general, the book may be commended to any student who requires to use the microscope for ordinary laboratory purposes or for research, as one that will afford him all the practical assistance he is likely to require in the course of his work.

Erosion of the Coast and its Prevention. By F. W. S. Stanton. Pp. 68. (London: St. Bride's Press, Ltd., n.d.) Price 3*s.* net.

THIS book is a reprint of a series of articles which recently appeared in *Public Works.*

It consists of five "parts," or chapters, relating respectively to general observations on coast erosion; the agents of destruction and construction, and their effects on the English coast; land reclamation and coast defence; with an appendix on the Thames estuary. There are several maps showing the coast of England and illustrations of defence works. The maps appear to have been reproduced from larger drawings, the writing and names of places being so diminished and indistinct as scarcely to be legible, even with the aid of a magnifying glass.

The contents of the book form an interesting summary of the condition of coast erosion and protection in England, suitable for a serial publication, but they are of too general and superficial a character to be of any use as a text-book on the subject, and contain no information of consequence that has not been more fully dealt with in books already published. The author does not appear to have made any use of the information contained in the evidence laid before the Coast Erosion Commission, and the fact of this commission being in existence is only once casually mentioned.

The author attributes the destruction of the coast, amongst other agencies, to the action of undercurrents below low water, and of submarine springs and "animal borers," and states that the consideration of such agents of destruction "leads to feelings approaching despair," and "bordering on consternation when the formation of the coast consists of glacial deposit, the London Clay and the like." It would have been more satisfactory if this theory had been supported by instances where this occurs. Although it is also stated that this class of erosion is beyond prevention, in another part of the book a solution of the difficulty is described as being effected by means of submerged chain cable groynes, and it is stated, on the authority of the inventor of this scheme, that these groynes have been laid on flat, sandy shores with excellent results. The locality where this has been done is not given, nor any particulars as to the condition of the shore before and after their use.

The Evolution of the Sciences. By L. Houllevigue. Translated from the French. Pp. 318. (London: T. Fisher Unwin, 1909.) Price 6*s.* 6*d.* net.

IN his preface to the English edition of his book, M. Houllevigue explains that it is not his object to teach men of science anything. "I only wish," he writes, "to interest those who love science as outsiders in the general ideas which form the atmosphere of the laboratory, and, above all, to make them familiar with that superior form of common sense which is called the scientific spirit." Nine subjects are dealt with—the tendencies of chemistry, transmutation and Sir William Ramsay's experiments, the existence of matter, the interior of the earth, the sun, eclipses, the Milky Way, the organisation of matter, and the frontiers of the sciences. Each essay presents the broad aspects of the subject surveyed, and is well calculated to set students thinking about fundamental principles of science. Judging from the absence of reference to work by Joly on radio-activity in relation to the age of the earth, Hale on his solar observations, Kapteyn and Eddington on star-drifts, and other researches of recent years connected with the subjects described, the author has not kept in close touch with all the points in which progress is now being effected.

History of Astronomy. By Prof. G. Forbes, F.R.S. Pp. ix+154; illustrated. (London: Watts and Co., 1909.) Price 1*s.* net.

IN this small volume Prof. Forbes describes the evolution of astronomical knowledge under three periods—the geometrical, the dynamical, and the physical. In addition, in book iii. he also describes the evolution of the instruments which have enabled astronomers of all ages to contribute to the store of knowledge on which our present-day astronomy is based.

The geometrical period covers the ages which elapsed between the time when man simply "wondered" and the time when his collected observations and knowledge had prepared the way for Kepler. This is a very interesting section, in which the methods and ideas of early astronomers are so clearly explained as to demand the attention of the general reader.

As a reference to ancient observations it should also prove valuable.

The dynamical period will appeal more to the student, its main theme being, of course, the establishment of the principles of universal gravitation by the work of Kepler, Newton, Laplace, Halley, and the others. The section on observation gives an abbreviated account of the methods and instruments employed in the more important and epoch-making researches, and contains a deal of interesting matter.

The fourth book, dealing with the physical period, is, perhaps, the least satisfying, but the chief reason for this, probably, is the confined space in which a tremendous amount of matter has to be discussed. As the author states on p. 147, he has been "compelled so often by the limits of space to stimulate without satisfying inquiry," and on these lines the book must be welcomed as a success. Those stimulated will find a useful, brief bibliography, to assist them in their further inquiries, given at the end of the volume.

W. E. R.

Wild Flowers and Trees of Colorado. By Dr. F. Ramaley. Pp. viii + 178. (Boulder, Colorado: A. A. Greenman, 1909.)

THIS book consists of two chapters, in the first of which the author presents a general sketch of the vegetation, and in the second he deals with the forests. Vegetation in the State of Colorado is exceedingly diverse by reason of the varied conditions of climate, and owing to the great variation in altitude the vertical distribution is more pronounced than the horizontal distribution, so that the author groups his associations according to the zones of elevation. There is little information regarding specific wild flowers beyond the illustrations of a dozen selected types and no systematic enumeration is supplied. The book is copiously illustrated with photographs of characteristic scenes or formations and the flowers referred to, making the text shorter than might be anticipated. The survey of the forest formations is more concrete, and twenty of the principal tree or shrubby genera are detailed with respect to the species and their diagnostic characters. The author announces the book as an introduction to Colorado botany, so that he may perhaps be subsequently induced to compile a flora of this interesting region.

(1) *The Historic Thames.* By Hilaire Belloc. Pp. 204. (London: J. M. Dent and Co., 1909.) Price 3*s*. 6*d*. net.

(2) *The Heart of England.* By E. Thomas. Pp. xi + 244. (London: J. M. Dent and Co., 1909.) Price 3*s*. 6*d*. net.

(1) THE first of these prettily-bound volumes is a new, cheaper edition of Mr. Belloc's essay on the Thames, which was issued originally in a limited edition, costing a guinea net. The Thames and its valley is dealt with from every point of view, and the interesting description reveals an intimate knowledge of the subject. The reader's task would have been easier had the book been divided into chapters; the index, notwithstanding its completeness, scarcely takes the place of a judicious division of the essay into sections according to subjects.

(2) The second volume is a similar re-issue of essays on subjects the most diverse. Ranging as they do from "Walking with Good Company" to "The Harvest Moon" or "Fishing Boats," they will make an appeal to readers who can enjoy something other than wild adventure or thrilling incident. Mr. Thomas does not treat his subjects too seriously, and to read his essays will give much the same pleasure as listening to bright, pleasant conversation in which quiet humour takes its proper place.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Are the Senses ever Vicarious?

THE interesting correspondence in NATURE of December 2 from Mr. G. I. Walker and Prof. McKendrick has reminded me of a passage in Nietzsche which will be found at the end of paragraph 192 of "Beyond Good and Evil." The passage has been translated as follows:—

"In an animated conversation I often see the face of the person with whom I am speaking so clearly and sharply defined before me, according to the thought he expresses, or which I believe to be evoked in his mind, that the degree of distinctness far exceeds the strength of my visual faculty—the delicacy of the play of the muscles and of the expression of the eyes must therefore be imagined by me. Probably the person put on quite a different expression or none at all."

Nietzsche's experience appears to suggest that a presentation, which is in form purely visual, may show evidence of a synthesis out of elements which are not solely of visual origin. No doubt, as Nietzsche says, the imagination plays an important part, and the same may be said of the memory; but Mr. Walker's experience seems to prove that in his case some of the elements out of which such a visual presentation are synthesised may be definitely of auditory origin. Perhaps to a psychologist this may not appear very surprising; but it certainly does seem a little surprising that, when the main source of Mr. Walker's visual experiences was cut off by the loss of his sight, the surviving auditory elements should alone be strong enough to continue to evoke presentations in visual form.

That the above is the explanation of Mr. Walker's experiences there seems little doubt. The play of expression which he "sees" will naturally follow the variations in the tone, &c., of the speaker's voice; but it is scarcely so certain that it will reproduce the actual expression of the speaker. As to the circumstance that Mr. Walker only "sees" the upper part of the speaker's face, as a rule, one may hazard the guess that this arises from the fact that in conversation the attention is generally concentrated on that part, with the result that the elements corresponding to it in the visual presentation are the most intense, and hence most likely to survive the destruction of their principal source. Presumably that which Mr. Walker sees is devoid of colour; but it would be interesting to know how the present intensity of his visual presentations compares with their intensity when he originally lost his sight.

Mr. Walker's preference for a position at an angle to the speaker possibly depends on the fact that he thereby secures a more marked difference between the sensations proceeding from the two ears—a difference analogous to the difference between the sensations received from the two eyes.

HUGH BIRRELL.

Holyrood House, Bo'ness, Linlithgowshire, N.B.,
December 8.

THE very interesting observations recorded in Mr. Walker's letter in NATURE of December 2 confirm in a remarkable manner the view I have always held, that in a very literal sense "seeing is believing"; that is, that a visual image is not an image on the retina, but a mental representation of what the percipient believes to be before him. As a rule, no doubt this mental representation is suggested by sense impressions coming *via* one or both optic nerves, but this is not necessarily the case; and it ought to cause Prof. McKendrick no surprise whatever to find Mr. Walker, though blind, perceiving visual images, which in his case are apparently suggested mainly by sense impressions coming through the auditory nerve.

There are, of course, plenty of arguments drawn from everyday life which point to the same conclusion, but which are so commonplace that we take them for granted without attempting to analyse their significance. I will mention one only. From my personal experience I am utterly unable to discover any distinction at the time of perception between a visual image in waking life and one in a vivid dream. It may be that afterwards I recognise that the latter were only baseless visions, but not, as a rule, from any quality or deficiency in the visual percept itself. I am aware that it has been suggested that even in dream images the retina is in some obscure way concerned, but this assumption seems to me quite gratuitous; it is not, so far as I know, supported by any evidence, and ought to be cut off by the razor of Occam.

Edward T. Dixon.

The Hard, Hythe, Southampton, December 5.

The Coloration of Birds' Eggs.

Without wishing to trespass further than I can help upon the space at disposal for discussing this topic, I may just explain that in my reply to Mr. Leslie, June 11, 1908, I distinctly gave it as my opinion that coloration had no connection with Mendelian principles. I concluded that coloration often depended on habitat, and was now useful as a means of protection; but the habitats (and nesting sites) of birds *change*, hence the anomalies met with which are cited as difficulties.

As to the colour-changes of the chameleon, Mr. Leslie ought to remember that this is an act of the animal itself, and a distinctly psychic act, in no way connected with reproduction. The coloration of the bird's egg is primarily the application of a pigment—depending in intensity on health and age—by the bird upon a *product* which has already ceased to form an integral part of the animal before the pigment is applied; and the bird's egg is not—like the mollusc's shell—an organic complement of the animal producing it. One might as well try to trace the evolution of a bird from the track of its foot in the sand as from the coloration of its egg!

So the parallel is inadmissible for this simple reason alone, apart from many others. Moreover, if number, form, size, texture in the shell itself have some morphological significance in relation to the bird's oviduct and secretory sacs, being also determined earlier in the phylogeny (as in the individual's ontogeny) of the group, coloration has little, except upon the selection and store of pigment; and the saurian and early avian eggs, furthermore, were uncoloured.

Thus coloration is a recent acquisition, which, as I have already pointed out, is intimately related—just as eggs and classification are, to some extent—to *habitat*, allied species (even genera or groups) laying allied types of eggs, adopting the same mode of life and nesting site. Thus it is a *physiological* adaptation, and as such cannot explain morphological origins, though as cause and effect we may compare coloration and protection from enemies, &c. In a word, coloration exists for concealment, and markings (*e.g.* the black blotch on the cuckoo's egg) for identification.

A. R. Horwood.

Leicester Corporation Museum, December 20.

THE CAPTURE AND TRAINING OF WILD ANIMALS.[1]

THE name of Carl Hagenbeck has attained such world-wide celebrity that a volume from the pen of the great animal-dealer and animal-tamer must surely receive a hearty welcome from the reading public. The publishers have therefore been well advised in bringing out an English edition of the original German work, although they might have taken care that it bore on the title-page some indication of its being from the pen of Mr. Hagenbeck himself. Whether the title is an exact translation of the German one we are unable to say, but if it be so, a slight modification would have been advisable, as it certainly does not read well in English. Neither, in spite of Dr. Mitchell's testimony as to the accuracy of their rendering, can we congratulate the translators on their style. "The menagerie owner Malforteiner" (p. 226) is not, for instance, elegant English; while a sentence on p. 153 conveys the astounding statement that Mr. Hagenbeck walked off with the fore-leg of a live elephant. On p. 157, as in many other places, we find "which" repeated in the first half of a very short sentence; and on p. 168 we find it stated that "this species is often captured, but in captivity they are very liable to die." On p. 58 the word "lime," in place of "bird-lime," completely spoils a sentence.

Mr. Hagenbeck commences his narrative with an account of his early life, in the course of which he tells his readers how he was initiated into the business of buying and exhibiting animals by his father, who took it up as a kind of supplement to his own proper trade late in life. When he once felt his feet, the author of the present volume forthwith proceeded to organise the trade of wild-beast catching on thoroughly business lines; and as he is the only man that has done so, the consequence is that he has practically monopolised the whole trade. Although it at times undoubtedly yields large profits, and is always full of interest to a man of enterprise and resource, the trade is full of risk, and demands great stability of character and perseverance in the face of losses on the part of those by whom it is conducted. We hear, for instance, of a loss of 10,000*l.* owing to disease seizing a collection of animals at the Crystal Palace for which that sum had been offered; while a sum of 5000*l.* was lost in two unsuccessful expeditions dispatched to Central Asia for the purpose of capturing argali sheep. The sheep were, indeed, captured right enough, but all died on the way home.

Young Walruses at Stellingen. From Hagenbeck's "Beasts and Men."

One of Mr. Hagenbeck's periods of great prosperity took place in the middle 'sixties and up to 1876, when an enormous number of live animals was brought out of the Egyptian Sudan. The menageries of the world were, however, overstocked, and about the year 1877 the author had almost to give away giraffes: this state of affairs induced him to take up the exhibition and training of animals in an establishment of his own—a branch of his business which culminated in the inauguration of the present animal-park at Stellingen. One of his earliest experiments in this direction was the exhibition of a herd of reindeer in charge of a party of Lapps, an exhibition which led to the importation of parties of natives from many other parts of the world.

---

[1] "Beasts and Men, being Carl Hagenbeck's Experiences for Half a Century among Wild Animals." An abridged translation by H. S. R. Elliot and A. G. Thacker, with an introduction by P. Chalmers Mitchell. Pp. xiii+299; illustrated. (London: Longmans, Green and Co., 1909.) Price 12*s.* 6*d.* net.

Either personally or by means of his representatives, Mr. Hagenbeck has explored a very large portion of the globe, having brought home, and reared, walruses from Greenland, giraffes, elephants, and rhinoceroses from the heart of Africa, tigers and sambar from the jungles of India, and wild horses and onagers from the fringe of the Gobi desert. The most interesting chapters in the book are undoubtedly those in which the author describes the various methods of capturing wild animals alive, and the behaviour and habits of particular species and groups. Did space permit, we might refer to many stories of adventures and escapes, but we must be content with mentioning one case where a party of some 3000 baboons attacked and beat off the captors of their fellows. These baboons, like many carnivora, are captured as adults by means of traps; but in the case of the larger herbivores Mr. Hagenbeck's most successful method is to train the natives (if they require it) to ride in pursuit of the herds until the young ones are brought to a standstill.

The book, which deserves a fuller notice than can be given here, is rich in interest from beginning to end; and should be of considerable value to all the custodians of zoological gardens. R. L.

THE SEXTO-DECIMAL YEAR OF BRITISH CALENDARS.

In searching English and Welsh calendars for sequences of festivals at intervals corresponding with the sun's stations on quarter and half-quarter days, or, in other words, the quarter days of both the solstitial and the May years—the octave year consisting of eight half-quarters—I find another octave year definitely marked in the calendars, and to a large extent still observed by festivals and fairs. The year of British calendars is definitely sexto-decimal, both the solstitial and May quarter days being duplicated, with the striking result that the eight half-half-quarter days coincide within three days of the exact half-half-quarter stations of the sun, the unit interval being roughly three weeks. The interval between a solstitial and a May quarter day being roughly six weeks, the duplicate octave year may be called an intermediate year.

The intermediate year is evidently the oldest octave of the two. It is the year as observed previously to the publication of the Julian calendar. Its basis was a calendar which was not corrected for the precession of the equinoxes, but which in other respects has been kept up to date. Calendars of other countries present similar anachronisms, but the persistence in Britain of such a belated calendar calls for special notice.

The jumbling together of two festival reckonings, on bases two thousand years apart, has resulted in a strikingly symmetrical sexto-decimal year. The festivals of the older octave were accurately fixed on solar quarter and half-quarter days, a fact which implies either the continued use of astronomical monuments for solar or stellar observation on those days, or a computation based on the exact length of the year. Within the Christian era, the festivals of the older reckoning drifted out of correspondence with the original solar stations. When the dates of the older sequence of festivals were marked in the Julian calendar, it was found—and I think it is hardly possible that the fact could have been overlooked—that the dates were just midway between the solar stations of a Julian sequence of festivals, and it became possible to utilise the half-half-quarter stations of the sun to indicate the incidence of the belated festivals. What makes the subject still more interesting is the discovery by Sir Norman Lockyer and others of indications of similar half-time dates in monument measures (Nature, November 12, 1908, p. 36).

A complete sexto-decimal solar year may be expressed as follows, the nearest round number of minutes of declination being given:—

Sun's decl.		Dates
N. 23° 30′ E.	... ...	June 22
,, 21 30 ,,	... ...	May 29–30, July 16
,, 16 20 ,,	... ...	May 6, August 8
,, 8 30 ,,	... ...	April 12–13, September 1–2
East	... ...	March 21, September 23
S. 8° 30′ E.	... ...	February 27–28, October 15–16
,, 16 20 ,,	... ...	November 8, February 4
,, 21 30 ,,	... ...	November 30, January 13–14
,, 23 30 ,,	... ...	December 23

Half-quarters of the Older Octave.

Date	Dedication	Character of Festival
November 30	Andrew	All Hallows
January 13...	Hilary	Winter solstice
February 28	Oswald	Candlemas
March 1 ...	David	
April 15 ...	Oswald	Vernal equinox
June 1... ...	Tekla	May day
July 15 ...	Swithin	Summer solstice
,, 17 ...	Kenelm	
September 1	Giles	Lammas
October 15...	Ulfrann	Autumnal equinox
,, 17...	Etheldreda	
,, 18...	Luke	

When the older octave only was marked in a calendar, such a calendar was doubtless a lunar one, and sometimes the interval between two festivals exactly corresponds with the solar interval only in a lunar reckoning. For instance, January 13–April 13 represents in the Roman lunar calendar the exact interval between the winter solstice and the vernal equinox, both dates being also Ides.

The intermediate year is clearly a May one, the first quarter, November–February, being rounded by the patron saints of Scotland and Wales. There is abundant evidence of St. Andrew's having been observed as New Year's Day. The interval between St. David's Day and St. Andrew's corresponds to the length of the vegetation year pure and simple. I think St. Patrick's Day, March 17, represents, like St. David's, a Candlemas festival, by a lunar calculation like that of the Coligny calendar. That date about the ninth century coincided with the vernal equinox, when it seems to have been given an equinoctial significance in connection with the commemoration of St. Patrick; but the shamrock, like the date, is reminiscent of a Candlemas festival (Nature, July 25, 1907, p. 295).

In one parish in Glamorgan—namely, Llangeinor—the complete sexto-decimal year was, until recently, observed by holding a court every three weeks. The patronal day is October 8, three weeks before All Hallows, but originally an autumnal equinox festival.

There is much evidence to show that the Scandinavian and German invaders of England, on the one hand, and the Welsh-speaking invaders of Wales from the north in post-Roman times, are chiefly responsible for fixing permanently the intermediate year in our calendar. So much is indicated by the list of saints commemorated, but more particularly by the association in Wales of half-half-quarter fairs with traces of northern and Scandinavian settlements

While in Wales generally hiring fairs are held in May and November, in districts like South Pembroke, known to have been occupied by Scandinavians, the hiring fairs are in April and October, and they represent an old equinoctial division of the year.

John Griffith.

MARINE INVESTIGATIONS IN NORWAY.[1]

THE work done by the Norwegians takes a foremost place amongst the fishery and marine investigations which have been carried out in recent years under the general guidance of the International Council, which was established in 1901 to coordinate the researches of the different countries bordering on the North Sea. The present report gives a general review of this work in readable form, without being burdened with any excess of detail, such detail being reserved for special memoirs, some of which are already published.

The introductory account of the plan and organisation of the work is written by Dr. Johan Hjort, the director of the investigations, and sets forth in the clearest way that effective combination of precise and accurate scientific investigation with practical developments of commercial fisheries which has always specially characterised the work of this investigator. Hydrographical investigation, plankton research, the study of the bottom fauna, each has received its due share of care and attention equally with the study of the natural history of fishes and the experiments which have led to the establishment of new fisheries for cod and for deep-sea prawns off the Norwegian coast.

In one important respect Norway has been especially fortunate, that is in having had the use of a research steamer, the *Michael Sars*, designed and built for the particular work of fishery research, an advantage which a parsimonious Government has denied to those who have to carry out similar work in England and Scotland. A detailed description of this vessel and her special equipment is given by Dr. Hjort, and the efficient and seamanlike way in which she must have been used could not have been better brought out than by the illustration showing the arrangement adopted for working two Petersen young-fish trawls and five tow-nets at the same time, and each at a different water-level. Equally striking are the successful results obtained by working a 50-foot otter trawl at depths of from 400 to nearly 700 fathoms.

The section of the review dealing with hydrographical investigations, by Dr. B. Helland-Hansen, summarises the results which have been reached by a study of the salinities, temperatures, and currents of the Norwegian Sea. In the concluding paragraphs of the section attention is directed to a series of striking correlations between the hydrographical conditions prevailing in the Norwegian Sea and various climatic, fishery, and other phenomena, which appear to be affected by these conditions. Evidence is given for thinking that the amount of heat which the Gulf Stream conveys into the Norwegian Sea has a controlling influence on the winter climate of Scandinavia. From the amount of warmth in the water, recorded as early as the month of May, the author considers that it should be possible to tell whether the succeeding winter will be warmer or colder than usual. For the years 1902–6, in which the investigations took place, a low temperature in the Gulf Stream in the southern portion of the Norwegian Sea in May was followed by an early fishing for cod in Lofoten in the next winter, and *vice versa*. Other correlations of a similar character are also described.

In dealing with the plankton investigations, Dr. Damas gives an interesting account of his observations on the distribution of the medusa, *Cyanea capillata*, which is of considerable importance from its intimate association with the fry of the haddock, whiting, and cod. The fry of these fishes shelter themselves under the disc of the jelly-fishes, and are borne along with the latter in their passive wanderings. Shoals of these Cyanea have been traced from the shores of Jutland into the Skagerak, and thence along the coast of Norway to the north, carrying the young fish with them. Another medusa, *Cyanea lamarcki*, which has its home in the temperate Atlantic, occasionally reaches the west coast of Norway, accompanied by the fry of southern gadoid fishes, poor-cod, pout, and pollack.

But in addition to the more indirect, though not therefore less important or less fruitful, ways of approaching fishery problems, represented by the hydrographical and plankton investigations just mentioned, the Norwegians have devoted very considerable attention to the natural history of the fishes themselves. Dr. Damas writes on the distribution of the eggs and young stages of the gadoids, and gives also many results of the greatest significance concerning the age and growth of these fishes. By an examination of the scales it is now possible to determine with considerable certainty the age of each individual fish. Many catches of cod and haddock were examined in detail in this way, and the number of fish belonging to each year-group was ascertained. The important fact has been determined that fishes born in certain years largely preponderate in the catches, and the effect of these favourable breeding years can be traced in the catches year after year. Similar results have been obtained by Knut Dahl in the case of the herring. Thus in a sample of spring herring examined in the spring of 1907 the eight-year-old fish were in remarkable abundance. The same year-class, in the autumn of 1907, was the most numerous of all the thirteen year-classes which composed the large herring of the coast of Helgeland. In the spring of 1908 several thousand spring herring were examined, and the nine-year-old fish were conspicuously abundant. In the autumn of 1908, in a large sample of herring from Kristiansund, it was found that the 9½-year-old fish were more numerous than either the preceding or succeeding year-classes. In samples from the North Sea and Skagerak the data appear to indicate that here, also, the same year-class predominated. It is clear that knowledge of this kind, if regularly and systematically collected, will enable estimates of the yield of the fisheries to be made some years before the fishing actually takes place, a result which cannot but be regarded as a triumph for the scientific method of approaching fishery problems.

Space has only allowed us to touch upon a few of the more striking features of this report. One would imagine that a perusal of it must convince the most sceptical of the value of the new knowledge which is now being rapidly made available as the result of the labours of the International Council for the Study of the Sea. Unfortunately, in this country the continuation of the work still, to some extent, hangs in the balance, but it is to be hoped that our Government, representing as it does by far the largest fishery interest of the countries bordering on the North Sea, will be induced to take a broad view of its responsibilities.

THE SURVEY OF INDIA.[1]

THE report on the operations of the Survey of India for the year 1907–8, in addition to the usual record of map-making of a utilitarian character, contains several features of scientific interest. We have long been accustomed to a high standard of work from this department, and it cannot be other than a subject of congratulation that we should see evidence, not only of the maintenance of its previous level, but also of continuous advance. The most recently completed geodetic triangulation, extending for a distance of 480 miles from the Indus to the peak Koh-i-Malik Siah, the junction point of India, Persia, and Afghanistan, is the most accurate operation of its class ever carried out in any country. Computed by the ordinary methods, the probable error of a single angle is 0″·21, a quantity not much more than half that of the corresponding figure obtained in any triangulation outside India.

This series of triangles carries the geodetic work to a point marking the most westerly limit reached by the principal triangulation of India. At this distance from the centre of the network the errors of the assumed spheroid become noticeable. Thus the astronomical azimuths observed along this line are consistently smaller than the azimuths computed from the triangulation, showing that the computation is taking the points too far to the north, *i.e.* that the curvature of the spheroid used for the reductions is, over this region, appreciably greater than that of the true geoid.

Pendulum operations were carried on during the year with the special object of ascertaining whether the force of gravity would be found in defect in submontane tracts in the south of India to the same degree as in the Himalayan region. In all cases the deficiency was found to be considerably less at these stations than at places of similar altitude in the north. It was also found that for stations on "isolated" hill-masses the degree of compensation of the visible mass is much less than it is on Himalayan stations. From this the general inference is drawn that it is chiefly the subjacent masses that affect the compensation of those visible on the surface.

All this is quite in accordance with the theory, first advanced by Osmond Fisher, that the "roots" of mountain masses are broader and shallower than the mountains themselves. The time is not far distant when it will be possible to draw an approximate section of these roots. It would be interesting to attempt this, in the first instance, by selecting a mountain, of as great a mass as can be found rising abruptly in a flat country, and carrying out a detailed gravimetric survey of the whole area, including the mountain and the flat region, for a considerable distance from it.

The year under review marks an important epoch in the history of the magnetic operations in India in that the preliminary magnetic survey was completed over the whole country with the exception of some frontier regions. Three iso-magnetic charts are published in the report, showing respectively (1) isogonals, and lines of equal secular change of declination; (2) isoclinals; (3) lines of equal horizontal force. During the current year the beginning of the detailed magnetic survey was projected.

Among other points of interest we may note a re-standardisation, with the international metre at Sèvres, of Colonel Everest's old 10-foot standard, indicating that no appreciable change has taken place in the lengths of the Indian standard bars during the last forty years.

Latitude observations were made with the view of eliciting some information as to the cause of the abnormally high deflection of the level found at Chaniana. It was observed that the deflection diminished rapidly in every direction from the apparent centre, and the conclusion is drawn that its magnitude originates "in a purely local cause, situated either at the surface or at a small distance below it."

E. H. H.

NIGERIA AND ITS PLANTS.

THE first part of an account of "The Useful Plants of Nigeria," written by Mr. J. H. Holland, now of Kew, but sometime curator at Calabar, appears as one of the Bulletins of Miscellaneous Information (Additional Series, ix.) recently issued by the Royal Botanic Gardens, Kew. A brief outline of the history of Nigeria is given in the bulletin, followed by a survey of the physical features, climate, peoples, botany, agriculture, and forestry, and finally the first part of the account of the useful plants of Nigeria.

Mr. Holland complains that "all the maps constructed so far have been compiled in England from sketches made at various times by numerous surveyors independently of each other." This must have been written some years ago, as Government surveyors have been at work since 1902, both in Lagos and southern Nigeria, and some very good maps have been compiled and issued both by the Survey and the Intelligence Department since 1906. In this connection southern Nigeria has to be congratulated on the excellent work done by skilled native surveyors who have been trained on the coast by the heads of these departments.

It is only too true that the entrance to most of the rivers is too shallow to admit steamers of any great draught, but it has to be remembered that this difficulty has to a certain extent been met by the remarkable build of Messrs. Elder Dempster's steamers, and so far as Lagos is concerned by the indomitable will of Governor Egerton, who already has two great dredgers at work on the Lagos bar. Much larger steamers are now entering the Lagos lagoon, and the hope is that passengers for Lagos who are now transferred from the ocean-going steamers to branch boats will soon be able to land direct on the marina. When these difficulties are overcome, and the railway, already open as far as Jebba and beyond, reaches the hinterland of northern Nigeria, Europe will have easy access to a climate described by Mr. Holland as bracing and delightful, and a country rich in agricultural and mineral wealth.

Under the heading "Climate," Mr. Holland touches on the remarkable difference between the rainfall on the coast and the interior; "during 1906 the maximum rainfall was 251·49 ins. at Egwanga, and the minimum at Olokemeji 40·92 ins." The latter place is only ninety miles from the coast. The author also mentions the Harmattan, a wind which comes from the north-east, across the Sahara desert, characterised by excessive dryness. This wind is prevalent during the dry season, and it is this break in the seasons and this Harmattan that we fear are going to decrease the yield of latex of the Para (*Hevea brasiliensis*) introduced from Ceylon. The Director of Agriculture for the French Colonies on the West Coast of Africa is said to be satisfied, so far as the coast is concerned, that *Hevea brasiliensis* is not going to be a success. We know that the trees at Aburi, on the Gold Coast, have ceased to yield latex. From experiments, however, in southern Nigeria on trees nearly eight years old, it is expected that the yield per tree will be more than that now given by the native tree (*Funtumia elastica*), but less than that extracted in Ceylon or other places where this break does not occur.

---

[1] General Report on the Operations of the Survey of India, administered under the Government of India during 1907-8. Prepared under the direction of Colonel F. B. Longe, R.E. Pp. iv+62, and maps. (Calcutta: Government Printing Office, 1909.) Price 3*s*.

Mr. Holland, under the heading "Botany," touches on the remarkable "increase of our knowledge of the flora of Tropical Africa," which he says "is due to several causes. Old collections

> "of very considerable extent which had only casually and partially been studied have now been worked up systematically (*e.g.*, Barter's West African, Schweinfurth's Sudan, and Welwitsch's Angola collections); fresh collections have poured in as new countries were opened up or the establishment of botanical stations in the older colonies facilitated a more exhaustive exploration of their neighbourhood; finally, it was just then Germany started with remarkable and well-directed energy on the botanical survey of her colonies, with the result that in not a few orders 50 per cent. or more of all the additions from recent collections are due to her enterprise."

Anyone who has resided in Nigeria, and has had other duties to attend to, must have had cause to bemoan his inability to make satisfactory horticultural, museum, or herbarium collections; well, in this book he will find full instructions how to make them, though the reader, while thankful to Mr. Holland, will still wonder why Hooker's country has not had the enterprise to do the same as Germany.

The botanical station at Ebutemeta, formed in 1887, has been reduced very greatly in area owing to the needs of the fast developing Lagos Railway, and as it cannot be extended in any direction, has almost ceased to be a distributing centre. But we may fairly conclude that the department's work has not been in vain from the following advertisement in the *Nigerian Chronicle*, October 22, 1909:—"FLOWERS, FLOWERS, FLOWERS! Apply to ONOFUNMI GARDENS, FAJI MARKET."

Olokemeji has quite taken the place of the gardens at Ebutemeta, and is a very large distributing centre. It has become the headquarters of the Forestry Department in southern Nigeria. Native pupils are being trained as agricultural and forest instructors in this interesting spot, once a great Abeokuta war camp. We note the omission of a plan of the gardens and reserve at Olokemeji, but plans are included of the now famous gardens in Calabar, which the author had so much to do in founding, and also of the plantations at Onitsha. He also gives a very interesting historical account of the founding of these botanical stations, and finally of the origin of forest conservancy in Nigeria.

The first part of this interesting publication closes with an incompleted list of the useful plants of Nigeria, a work long looked for by all those interested in the economic development of this remarkable dependency of Great Britain. Wherever we may happen to open this instructive book and commence reading we are at once interested, for be the subject fruit or seed, fibre or timber, the author has so much to say of their virtues and uses that we are for the moment apt to forget all sordid difficulties and to wonder how it is more fortunes have not been made in Nigeria. For instance, the author, describing the *Lophira alata*, writes:—"The wood is very hard and heavy . . . described in the trade as a first-class heavy fancy wood; used for furniture and turnery (Mus. Kew). Admiralty experts have valued it as better than teak (*Tectona grandis*), at about 8*d*. per foot." Now, knowing that this wood is very abundant in Nigeria, timber merchants there have shipped it home, and instead of the expected 8*d*. have had to receive 2½*d*. or 3*d*. If the Admiralty or any buyer in Europe would guarantee the merchants in Nigeria 5*d*. per foot for this timber the buyer could rely on a constant supply, and the merchants would make their fortunes. It is the varying uncertainty in the price of mahogany that makes the timber trade such a dangerous one for the merchant, and is perhaps one of the causes why the Forest Department has been urged to start plantations of teak, plantations, by the way, which are so far doing extremely well.

The need that Mr. Holland has so ably endeavoured to satisfy is a really great one, and we can only hope that the reception of his book by the public—so keen on the natural products of Nigeria—will be such that he will soon be tempted to give us another edition of "The Useful Plants of Nigeria," as full as possible of illustrations.

EUGENICS, MENDELISM, AND BIOMETRY.[1]

NOW that the public has become familiar with the word eugenics, it is right that an exposition of its meaning by Sir Francis Galton, the founder of the science, should be easily accessible, and this the Eugenics Education Society has wisely provided by the publication of "Essays in Eugenics." The first essay is on "The Improvement of the Human Breed, under Existing Conditions of Law and Sentiment." It was delivered as the second Huxley lecture before the Anthropological Institute on October 29, 1901. Then follow "Eugenics: its Definition, Scope, and Aims," "Restrictions in Marriage," "Studies in National Eugenics," and "Eugenics as a Factor in Religion," read before the Sociological Society in 1904 and onwards. After this comes the Herbert Spencer lecture delivered before the University of Oxford in 1907, on "Probability, the Foundation of Eugenics," and the volume is concluded by an address to a meeting of the Eugenics Education Society in 1908 on "Local Associations for Promoting Eugenics." The volume, of which the titles quoted give an indication of the contents, forms an admirable introduction to the subject. The host of objections which immediately spring to the mind and tongue of ordinary educated people on first receiving the idea of conscious selective breeding in man are here met with easily intelligible arguments and with common sense. It is to this and to the moderation with which the author expounds his thesis that the present wide realisation of its practicability must be due.

The *Mendel Journal*, of which the first number appeared in October, has been founded in order "that Mendelism shall be presented to a wider public by men who believe in its truth, foresee its future, and who recognise their responsibilities in the work they do," also in order "to gather for the science of genetics a harvest rich in facts relating to human pedigrees and the inheritance of normal characters as well as of peculiarities," and finally "to make it a medium by which authoritative advice and direction may be given in the form of answers to questions upon matters of general interest relating to problems of cattle, cereal and plant breeding."

More than one-third of the number is taken up by an address by Mr. G. P. Mudge, entitled "Biological Iconoclasm, Mendelian Inheritance and Human Society," delivered to the Mendel Society and to the Eugenics Education Society in June, 1908.

Like many lecturers on eugenics, Mr. Mudge realised that in order to convince people of the supremely important part played by heredity in determining physical and mental characters in man, it was necessary to free their minds from common error that the predominant determining factor is environment. His method of attempting to do this is vigorous assertion, unsupported by any direct evidence. That improved bodily conditions and suitable education can effect a great improvement in even the least promising human material is a belief widely and probably correctly held; yet Mr. Mudge tries to shake it by arguments such as the following:—"From the fertilised ovum of a fish there is developed a fish, not a bird. Transference of the bird to water, or the fish to the skies, will not convert the one to the other." He complains of others "setting up a dogma that rushes in where biological philosophy fears to tread," but his own biological philosophy is none too diffident, and indeed bears a striking resemblance to dogma. His failure to produce direct evidence as to the relative effects of heredity and environment in man is no doubt due to the fact that very little evidence is available, but this should be frankly acknowledged.

---

[1] (1) "Essays in Eugenics." By Sir Francis Galton, F.R.S. Pp. vi+109. (London: The Eugenics Education Society, 1909.)

(2) *The Mendel Journal*, No. 1, October, 1909. Pp. 216. (London and Manchester: Published for the Mendel Society by Taylor, Garnett, Evans, and Co.) Price 2*s*. 6*d*. net.

(3) *Biometrika*, vol. vii., parts i. and ii., July and October, 1909. Pp. 236. (Cambridge: University Press.) Price 20*s*. net.

Mr. Mudge then goes on to describe very fully and clearly a simple case of Mendelian inheritance in rabbits, and mentions certain phenomena of inheritance in man which are explicable on a Mendelian hypothesis. He concludes with what is in effect a plea for eugenics, which for him seems to follow as a corollary to Mendelism. To us it appears that he would be more likely to win proselytes if he had rested his case on the broader basis of the generally admitted facts of human inheritance. For although in certain cases these may bear a Mendelian interpretation, it cannot be argued that Mendel's laws have been demonstrated at all widely for man; and it is certain that they have not been demonstrated for any of the characters which constitute civic worth.

Two other papers read to the Mendel Society are included in the journal, namely, J. T. Cunningham, "The Evolution of Man," and C. C. Hurst, "Mendelism and Sex." Original research is represented by "Parthenogenesis in Nicotiana," by Mrs. R. Haig Thomas. Among other contributions from G. P. Mudge are three family histories described in careful detail. These are the first of "Mendelian Collection of Human Pedigrees," which appears as a sort of rival to the "Treasury of Human Inheritance," issued by the Galton Research Laboratory in National Eugenics.

Under the heading "Methods and Results" are included three papers by "Ardent Mendelian"; of these the first calls for special comment. It purports to deal with the "present position of Mendelians and Biometricians." Its meaning looms a little vaguely from a cloud of martial imagery, in which biometricians are represented as an army unsuccessfully resisting the encroachments of Mendelians. The author appears to us completely to misunderstand the position of biometricians, which is simply this, namely, that statistical methods may be applied with advantage to the study of many biological problems, including that of heredity; they do not hold that these methods should be applied to the exclusion of others, such as the Mendelian; and the validity of the statistical descriptions obtained by the correct application of their methods would be in no way impaired, even if Mendel's laws were proved to be universally true. We regret to note that the tone of this article is calculated to be offensive to biometricians; as an instance the following sentence may be taken:—"We may further infer, therefore, that the discipline of the army is very severe, and perhaps this may throw some light upon the constant reappearance of the figure 0·5 in relation to the size of some of its artillery equipment." Since 0·5 is the value obtained very frequently as a fraternal correlation coefficient, it must be assumed that "Ardent Mendelian" means that this agreement is, to put it crudely, the result of "faking." If serious charges of this kind are to be made, they should be made in plain English, and supported by strong evidence. We do not know whether the *Mendel Journal* has an editor; if it has, we venture to suggest to him that it will not lose in dignity or influence by adopting a more courteous tone. It starts with a clean sheet, and need not perpetuate the bitterness engendered by old controversies.

We regret that space does not permit us to deal with the many interesting papers published in this double number of *Biometrika*, but will make reference to two only selected from them. Dr. Galloway gives an account of his seventeen years' experience of canary breeding, with a partial analysis of the results. His conclusions, valuable in themselves, together with the clear descriptions and figures which he gives of the different points of the various breeds of canaries, should be of the utmost assistance to anyone proposing to breed these birds, either as a fancier or for the purpose of studying the problems of heredity.

Dr. Jenkinson deals with the relation between the symmetry of the egg, the symmetry of segmentation, and the symmetry of the embryo in the frog; he finds that "the position of the symmetry plane of the egg is determined, in the absence of external factors, by the path of entrance of the spermatozoon, and the point of the entrance is nearly always opposite to the grey crescent. The position of the first furrow is determined by the second part of the sperm path, the line of union of the male and female pronuclei. Thus the internal factors which determine differentiation and the direction of cell-division are not the same, although they may coincide (when the two parts of the path lie in the same meridional plane). They are also influenced differently by different external factors." It appears that there is always a closer relation between the plane of symmetry of the unsegmented egg and the sagittal plane of the embryo than between the first furrow and either of them.

E. H. J. S.

DR. SHELFORD BIDWELL, F.R.S.

SHELFORD BIDWELL was a distinguished member of that class of men to whom English science owes so much, the amateur, who, holding no post as a professional scientific man or teacher, by voluntary devotion enriches science with investigations of permanent value.

Born at Thetford in 1848, and trained at Caius College, Cambridge, he was placed among the Junior Optimes in the Mathematical Tripos of 1870, and in the following year he obtained second-class honours in the Law and History Tripos. He read for the profession of law at Lincoln's Inn and was called to the bar in 1874. While he was practising as a barrister he cultivated his taste for physical science, and was attracted to the meetings of the then newly founded Physical Society, which he joined in the spring of 1877. Years afterwards, in his presidential address of 1898 to that society, he referred to the matter in the following terms:—

"One of the most useful functions of these institutions (the Physical and other kindred societies) is to bring together and promote friendly intercourse among fellow-workers in a particular branch of science. In this connection, I myself (if you will pardon me for referring to personal matters) owe a heavy debt of gratitude to the Physical Society. At the time when I was desirous of becoming a member, I was not personally known to a single man who was in a position to support my candidature. After some preliminary correspondence, I introduced myself to

Prof. Roberts-Austen, then one of the secretaries; he kindly gave me an introduction to Prof. Adams, the president, and the two were good enough to sign my recommendation form. Who furnished the third signature I never ascertained. In spite of this somewhat inauspicious *début*, it was my good fortune after, and solely as the result of, a few years' more or less regular attendance at the meetings to have made a large number of acquaintances, and, I may say, very good friends, among the leaders and workers in science. I have long regarded my connection with the Physical Society as the source of one of the chief interests of my life; and for the highly valued honour you have done me in electing me to be your president, I cannot sufficiently express my thanks."

Bidwell's first communication to the Physical Society was read on March 13, 1880; it was entitled "On the Influence of Friction upon the Generation of a Voltaic Current," and was a simple investigation into the causes of the operation of the Edison "motograph" or chalk-cylinder telephone receiver. He considered his experiments to show conclusively that the explanation of the changes of friction in that instrument is the electrolytic liberation of a film of hydrogen gas. For the next three or four years he was chiefly occupied which the photo-electric properties of selenium. He invented a method of telegraphic photography based on the use of selenium. In the course of his work he did much to clear up the obscurities and contradictions which until then had hung over the behaviour of selenium. Being himself an excellent mechanic, and having equipped for himself a workshop in his house, he constructed, with his own hands, many simple and beautiful experimental appliances. His method of constructing selenium cells with copper wires wound upon a slip of slate or of mica brought selenium cells within the reach of all experimenters. He investigated the effects of temperature and of moisture upon selenium cells. He also investigated the kindred properties of cells made with mixtures of sulphur and carbon. The next subject to claim his attention was the alleged change in the resistance of carbon under pressure, which led him to a careful investigation of the whole question of microphonic contacts. In an article communicated to the Royal Society, he considered the methods of measuring the electrical resistance of contacts, and found that though the moment before the measurement is made the resistance may be sensibly infinite, the very act of measurement reduces it to a few hundred ohms. Here he touched the question of the coherer, which was destined in a short space to become, in the hands of Branly and of Sir Oliver Lodge, so vastly important for the study of radio-telegraphy.

Bidwell was always a most conscientious worker, never satisfied to publish until he had convinced himself of the reality of his results, and of their originality. He took endless pains to discover what might have been previously published on any subject at which he was working. He had a curious distrust of himself while at work, coupled with a singular confidence in the results when they were once established. He had a profound dissatisfaction with half-knowledge, but yet those subjects as to which knowledge was in an imperfect stage possessed for him a singular fascination. Most of his work consisted in unravelling paradoxical facts or obscure phenomena. Thus he investigated the magnetic expansion of iron, and cleared away the obscurity involved in the case of straight rods by the action of their poles, by showing that an iron ring (which possesses no poles) also expands on being magnetised. In connection with this subject, he re-examined the law of magnetic traction. He was the discoverer, too, of the paradoxical fact that an iron electromagnet, if its core is made of an iron tube with short plugs fitting loosely into its ends, when it is magnetised grows longer by pushing the plugs out, instead of attracting them in. Later, and by a beautifully refined piece of home-made apparatus, he showed that the impact of light is able to affect directly the magnetic state of a carefully demagnetised soft iron rod.

His attention was then directed to the subjective phenomena of vision, and he made innumerable experiments on the "ghosts" that are seen following in the train of a luminous body moving across a dark field. He produced some very extraordinary and paradoxical illustrations of colour-vision by intermittent illumination and vision of coloured objects, which he caused to appear of tints complementary to their actual pigments. The result of these investigations he embodied in a most interesting book, written in a popular style, but essentially scientific throughout, called "Curiosities of Light and Sight," published in 1899. He lectured more than once on these matters at the Royal Institution. Unhappily, in his experiments his eyesight became seriously impaired, and he was threatened with blindness. Fortunately, however, after many months he recovered, and was able to read without pain. In 1900, Bidwell received from his own University of Cambridge the degree of D.Sc. He had been elected a Fellow of the Royal Society in May, 1886; and he served on the council of that society from 1904 to 1906. His presidency of the Physical Society in 1897-9 has already been alluded to. Amongst his later work was the writing of the article on magnetism for the new volumes of the "Encyclopædia Britannica." In consequence of troubles arising from an affection of the heart, Shelford Bidwell had not been able to attend any scientific meetings for more than eighteen months, his last visit to the Royal Society being in May, 1908. He died on December 18 at his residence, "Beechmead," Oaklands Chase, Weybridge, at the age of sixty-one.

DR. R. BOWDLER SHARPE.

IT is with great regret that we have to record the death of Dr. Richard Bowdler Sharpe, at his residence in Chiswick, on December 25. Although Dr. Sharpe had been in indifferent health for some considerable time, he was on duty at the Natural History Museum at least as late as December 14, so that the fatal attack was of comparatively short duration.

Born in November, 1847, and therefore just over sixty-two years of age at the time of his death, Dr. Sharpe was the son of T. B. Sharpe, a publisher, of Cookham and Malvern Link. Educated at Brighton and at Peterborough and Loughborough grammar schools, he entered the service of Messrs. W. H. Smith and Son at the early age of sixteen, and after remaining two years with that firm, migrated in 1865 to the establishment of Mr. Quaritch. Two years later he was appointed to the newly-founded librarianship of the Zoological Society of London, a position which brought him into contact with Dr. P. L. Sclater, and thus no doubt tended to foster that taste for ornithology with which he had been imbued from very early years. Be this as it may, by 1872 Dr. Sharpe had become an accomplished ornithologist, and he was appointed in that year to a senior assistantship in the zoological department of the British Museum, a position from which he was promoted to an assistant-keepership in the vertebrate section in 1895, this latter post being held by him at the time of his death.

Dr. Sharpe was a Fellow of the Linnean and Zoological Societies, an LL.D. of Aberdeen University, and holder of the Emperor of Austria's gold medal for distinction in science; in 1905 he was president of the fourth Ornithological Congress, which met in London.

In addition to being joint author of the earlier portion of the "Birds of Europe" and sole author of various bird-monographs such as those of the kingfishers and birds-of-paradise, Dr. Sharpe compiled 13 out of the 27 volumes of the invaluable British Museum "Catalogue of Birds," and was responsible for the whole of the 5 volumes of the companion work, the "Hand-list of Birds," of which the last volume was completed only a short time before his death. As regards his knowledge of the external features of birds, and his capacity for identifying species, Dr. Sharpe was, if not unrivalled, at all events unsurpassed; and his preeminence in these respects received world-wide recognition. Unfortunately, he knew little of the anatomy of birds, so that in his address on "Attempts to Classify Birds," read before the second Ornithological Congress at Budapest, in 1891, he had to depend for this portion of his subject on information borrowed from Seebohm, who had in turn been mainly dependent upon Kitchen Parker. Under Dr. Sharpe's supervision, the collection of bird-skins in the British Museum increased by leaps and bounds, and has now attained vast dimensions, while it is specially valuable on account of the number of "types" it contains.

As a relaxation from his ornithological studies, Dr. Sharpe devoted, during the later years of his life, a considerable amount of time to the natural history and antiquities of Selborne, where he owned a cottage in which he spent much of his holidays. As the result of these leisure-time studies, he brought out a beautifully illustrated edition of "White's Selborne" in two thick volumes.

THE NATURAL HISTORY MUSEUM.

THE *Times* of December 28 includes further correspondence upon the question of the separation of the Natural History Museum from the British Museum. In the two letters subjoined, Prof. A. Sedgwick and Sir Ray Lankester reply to the letter of Sir Archibald Geikie, published in that journal on December 13, and reprinted in NATURE of December 16.

I much regret that it should be necessary for me to address you again on the subject of the Natural History Museum, but the publication of the correspondence between Mr. Lowther and Sir Archibald Geikie in your issue of December 13 last leaves me no alternative. The only satisfactory thing about the correspondence is the admission by Mr. Lowther that the Trustees are uneasy in their own minds as to the satisfactoriness of the present arrangements. They "are anxious to be reassured," Mr. Lowther writes, "that the management of the Natural History Museum is adequate." This is a sign of grace, if only a small one, but such as it is we are thankful to have obtained it.

Before proceeding to deal with Sir Archibald Geikie's letter, there are two small points to which I desire to call the attention of your readers. The first of these concerns the views of the Trustees as to the proper person to call in for judgment in a matter directly concerning the administration of the Museum. They call in one of their own body. This seems to me to constitute a new departure in judicial procedure. The second is the fact that the President of the Royal Society, in his capacity as Trustee, has allowed himself to be nominated public censor of those of his colleagues who in the last forty years have expressed objections to the system which is under discussion. I also desire to emphasise the following points:—(1) In this prolonged agitation it has always been the system of administration, and not the persons administering the system, which has been impugned. (2) The living protagonists of the agitation hold that a system of control by Trustees is the best, provided that their number is small and that the scientific element, whether professional or other, is not represented as such (see NATURE, April 29, 1909, p. 254).

I now proceed to the consideration of Sir Archibald's letter. It is painful to me to have to call in question the deliberate statement of a much respected friend, and one who holds the high and honoured position of President of the Royal Society. It is hard to be certain of one's motives, but I believe that my sole motive in the present case is that of the interests of science. I also wish to say that I have the same belief as to the reasons which have induced Sir A. Geikie to write his remarkable letter. The issue between us, therefore, is simply one of fact, and can only be decided by an inquiry. I had hoped, especially after Mr. Montagu's letter to you of November 19, that the Trustees might be willing to set their own house in order, and that an inquiry might be avoided. I have not always held this view, and for two years, acting in conjunction with my colleagues, I pressed for an inquiry; but I came to see that there were many difficulties in the way of an inquiry and objections to the possible legislation which might result therefrom, and that the essential points in which we deemed the museum administration defective might be remedied by the action of the Trustees themselves. I therefore welcomed the suggestion in Mr. Montagu's letter, and wrote to you to say so. But so long as Sir Archibald's statements are accepted as authoritative, and so long as the Trustees think along the lines of Mr. Lowther's letter, it is clear that reform from within is impossible, and that an inquiry by impartial outsiders is a necessity.

As Sir Archibald Geikie says that he has made a "careful investigation of the facts of the case," we may presume that all his statements, particularly those which can be tested without any inquiry, will be accurate. Let us submit his letter to that test. His first statement is that the "agitation has been carried on fitfully but persistently in the public Press for many years, and has been supported by *some* well-known men of science" (the italics are mine). That Sir Archibald should have made this statement shows that his investigation has been, to say the least of it, superficial. The recent (during the last half-century) history of the agitation is as follows. In the year 1866 there was a memorial to the Chancellor of the Exchequer, signed by all the most famous biologists of the time (I will enumerate them when I deal with the word *some*), stating that they were "of opinion that it is of fundamental importance to the progress of Natural Sciences in this country that the administration of the national Natural History Collections should be separated from that of the Library and Art Collections, and placed under one officer, who should be immediately responsible to one of the Queen's Ministers." In the year 1874 the Royal Commission on Scientific Instruction and the Advancement of Science, having fully considered the state of the Natural History Departments in the British Museum and taken evidence thereon from the principal scientific authorities of the country, came to the same conclusion. In 1879 the Council of the British Association for the Advancement of Science prepared a memorial to the Prime Minister pointing out that the views of scientific men on this subject, as embodied in the recommendations of the Royal Commissioners, had been entirely overlooked, and that "the question of the administration of the Natural History Collections is one of the utmost importance as regards the future progress of Natural History in this country," and urging upon the Government to take the opportunity afforded by the removal to South Kensington "of effecting the alterations in the mode of administration of the Collections recommended by the Royal Commission." Now ensued a lull in the agitation for twenty years. The cause of this lull is highly instructive, and must be mentioned here. Hitherto the head of the Natural History Collections had been entitled Superintendent, and had been subordinate to the Principal Librarian. In 1885, on the recommendation of the Principal Librarian, Sir E. Bond, the office of Superintendent was replaced by a new office, that of Director, with new duties, new responsibilities, and new salary. The Director was made entirely independent of the Principal Librarian, except in financial matters. Financial independence was offered him, but declined. This meant that the Trustees had accepted the recommendations of the Duke of Devonshire's Commission so far as concerned the independence of the Museum. In 1898, on Sir W. Flower's retirement, it became known that the Trustees had in contemplation the revocation of the position of comparative independence assigned in 1885 to the Director of the Natural History Museum. Accordingly, a memorial was presented to the Trustees stating that, in the opinion of the memorialists, it was "of great importance to the welfare of Natural History that the principal officer in charge of the national collections relating to the subject should not be subordinate in authority to any other officer of the Museum." This memorial was published in the *Times* on July 9, 1898, and on the following day a letter appeared from the Principal Librarian stating that the petitioners had been misinformed, and that no change in the status of the Director was in contemplation. In spite of that public statement the fears of the memorialists were realised, for either in July or August of that year the position of comparative independence assigned to the Director of the Natural History Museum in 1885 was revoked, and the new Director who was appointed shortly after found himself—quite unexpectedly in view of the letter just referred to—in a position very different from that of his predecessor. In September, 1907, a memorial praying that advantage might be taken of the approaching vacancy in the Directorship to hold an inquiry into the administration of the Museum was sent to the Prime Minister, who in July, 1908, received a deputation on the same subject. As nothing resulted from this last effort, a letter was addressed to the *Times* on April 19 of this year calling the attention of the public to the matter. So much for the suggestion that the agitation on this matter has been a Press agitation.

I must now pass to consider the suggestion contained in the words "supported by *some* well-known men of science." The memorial of 1866 was signed by G. Bentham, W. B. Carpenter, W. S. Dallas, Charles Darwin, F. D. Godman, Joseph Hooker, T. H. Huxley, John Kirk, Lord Lilford, A. Newton, W. K. Porter, O. Salvin, P. L. Sclater, S. J. A. Salter, H. B. Tristram, A. R. Wallace and others. The Report of the Royal Commission was signed by the Duke of Devonshire, Sir J. Lubbock, Sir J. P. Kay-Shuttleworth, Dr. Sharpey, T. H. Huxley, G. G. Stokes, Prof. Henry Smith, Mr. B. Samuelson, Sir Norman Lockyer being Secretary. The memorial of the Council of the British Association was signed by W. Spottiswoode, Douglas Galton, P. L. Sclater, on behalf of the Council. The memorial to the Trustees in 1898 was signed by Lord Kelvin, G. G. Stokes, M. Foster, A. Rücker, John Murray, Francis Galton, Henry Thompson, W. Turner, Benjamin Baker, A. R. Wallace, W. F. R. Weldon, amongst others—I have not access to a complete list. The memorial of 1907 was signed by all the Professors of Zoology in the United Kingdom except two, and was supported by all of them. The deputation to the Prime Minister of 1908 consisted of some of these Professors, supported by Mr. Francis Darwin and Dr. Marr. From these lists it is clear that, although it would not be correct to say that this long-continued agitation has received the support of all well-known men of science, yet it would have been nearer the truth if Sir Archibald Geikie had used the word *most* instead of *some* in referring to the support it has received, for the cream of certainly two, and perhaps three, generations of English men of science have taken part in the agitation. Having thus shown that Sir A. Geikie has been inaccurate, not to say loose, in two of his statements of fact, what weight can be attached to any opinion that he formulates in his letter on the subject under discussion? He says that the result of his inquiry has been to convince him "that the agitation has no substantial justification, but has arisen from misapprehension and ignorance," and he goes on to reprove those who have taken part in it in these words:—"If the actual state of the matter had been realised no agitation ought ever to have been started." This is Sir Archibald Geikie's opinion. Let us try to realise for a moment what an extraordinary state of mind it reveals! What a contempt for his colleagues, some of them among the greatest naturalists of the world's history, not to mention great names in other branches of science, some of whom had made a special and prolonged inquiry as members of a Royal Commission specially deputed to deal with this matter, and were masters of administrative methods! His contempt for the knowledge and judgment of his most distinguished scientific contemporaries is so colossal that it almost touches the infinite. But I need not labour this point, nor need I refer to his estimate of the knowledge of those of his zoological colleagues now living, all of whom by their avocations have a special interest in the Museum.

We now come to the last and most important point of all. Sir Archibald says that "the allegation so constantly made, that the Director of the Natural History Museum is under much more than merely nominal control of the Director and Principal Librarian at Bloomsbury is without any real foundation." This, of course, is his opinion on the question which has always been at issue. We, that is my colleagues and myself, traverse it absolutely. Can it be supposed that all the distinguished men in the past whom I have mentioned, and all the biologists now living who have paid special attention to the matter, have undergone the labour and expenditure of time and money which this prolonged agitation has involved without convincing themselves of the reality of this basal element in the question? It is true they may be wrong and Sir Archibald right, but what, I ask all unprejudiced men, are the probabilities? It may be said in reply, "Yes, but what are your reasons for holding this view? You must at least state them." A most reasonable request, with which we are only too anxious to comply if the opportunity is given us. Unsupported statements are worth little, and may easily be turned into personal attacks and lead to useless and hurtful recriminations. An inquiry must be held before a proper tribunal which can receive and sift evidence on this question so important to biological science in England.

At the end of his letter Sir Archibald Geikie draws a red herring across the scent by referring to a matter which, however deeply we may feel it, we have always avoided. It is not the question at issue. That question existed long before the recent circumstances to which he refers arose, and will, unless dealt with, continue long after they are forgotten.

Adam Sedgwick.

Imperial College of Science and Technology,
December 20.

I am sure that everyone connected with natural history or with the Royal Society recognises the amiable tactfulness and discretion of our worthy President. These qualities explain the opinion which he has expressed in reply to an inquiry from the Speaker as to the government of the Natural History Museum. They do not, however, give any weight to it. The essential qualification for expressing an opinion of value on this subject is a knowledge of the facts. Of that, I am sorry to be obliged to say, Sir Archibald Geikie is entirely innocent. The Speaker says in his letter that he understands that Sir Archibald Geikie "has recently made special inquiries on this subject." Sir Archibald himself says he has "had occasion to make a careful investigation of the facts of the case."

Sir Archibald, though he has recently become a Trustee of the British Museum, has not become one of the inner circle of the standing committee. No doubt he supposes that he has acquired some knowledge of the "facts of the case." He has been permitted to see the Red Book of Regulations! But he does not duly estimate the secrecy with which the business of the Trustees is conducted by the standing committee. He knows so little of the matter that he is unaware of his own ignorance. There are only three people who really know the facts as to the proceedings of the Trustees of the British Museum in regard to the Natural History Departments during the last twelve years. The Trustees themselves, even those of the inner circle, do not understand what has been done in their name. Sir Archibald Geikie has not sought information from any one of the three persons who could (were they willing) give it. The individual who really knows every detail as to the actual government of the Natural History Museum by the Trustees of the British Museum during the last twelve years—whether good or bad in their tendency and result—is the late Director of the Natural History Departments. He is in frequent personal relations with Sir Archibald Geikie, but has never been consulted or questioned in any way whatever by that gentleman during his "careful investigation" of the utility or inutility of the present relations of the Trustees of the British Museum to the Natural History Museum.

I am able to state, categorically, that Sir Archibald's opinion is not based upon a knowledge of the facts, and that he has not (for reasons perhaps known to the Speaker and to himself, but not to me) taken the obvious means of ascertaining the facts—since I am the late Director in question. I have always maintained very friendly relations with Sir Archibald and should have been quite willing to assist him in his inquiry. He has not, however, approached me on the subject, and has not received either from me or from others authorised by me any statement on the matter. It will, I think, be obvious to your readers that no one, not even a member of the committee itself, which varies in consequence of absences, replacements by death, inattention, and incapacity to understand the matters discussed, can have such a knowledge of the acts and tendency of the body in question as the official (in this case the Director of the Natural History Departments) who during many successive years attended every meeting (held once a month) as secretary, prepared their agenda, took the minutes of their proceedings, and conducted their correspondence. He necessarily endeavoured to obtain their support for certain lines of policy, and knows, as he alone can know, what they accepted, what they rejected, and the motives and influences at work in determining their assent and their dissent. He cannot make a full statement of his knowledge on these matters except under very special authority and guarantee of immunity. For this he asks.

E. RAY LANKESTER.

Hôtel Ritz, Paris, December 16.

NOTES.

WE regret to announce the death, at eighty-two years of age, of M. Bouquet de la Grye, member of the Paris Academy of Sciences, and distinguished by his work in astronomy and hydrographic engineering.

THE death is announced, in his seventy-fourth year, of Prof. L. Lortet, honorary dean of the medical faculty in the University of Lyons and director of the Natural History Museum in that city. Prof. Lortet was the author of a number of original works, and also of translations of works by Prof. Tyndall and other British scientific writers.

THE juvenile lectures at the Royal Society of Arts will be delivered by Prof. Harold B. Dixon, F.R.S., on January 5 and 12, his subject being the chemistry of flame. The subject is one that lends itself to experiments, and the nature of flame, the properties of oxygen, the nature of various combinations of air and gas, will all be fully illustrated and explained.

THE Paris correspondent of the *Times* announces the death of Dr. L. Malassez, assistant director of the École des Hautes Études, and president of the French Biological Society, in his sixty-eighth year. Dr. Malassez was distinguished by his numerous works on normal and pathological histology and his research work on questions relating to blood tuberculosis and the genesis and nature of tumours.

BY the assassination, on December 22, of Mr. A. M. T. Jackson, Collector of Násik, the Bombay Civil Service has lost one of its most learned members. Educated at Winchester and Brasenose College, Oxford, where he gained the Boden Sanskrit scholarship, he commenced his Indian service in 1888. He was the contributor of many papers on subjects connected with the religion, history, and ethnology of western India, and he collaborated with the late Sir James Campbell in the valuable series of volumes constituting the "Bombay Gazetteer." It was mainly owing to his researches published in the *Indian Antiquary*, Journal of the Royal Asiatic Society, and articles in the "Bombay Gazetteer" that the origin of the Rájput tribes from the Scythian and Hun invaders was established. His untimely death removes one of the most eminent scholars in the ranks of the Indian Civil Service.

THE Research Defence Society desires to direct the attention of all Parliamentary candidates to its work. The society was founded in January, 1908, to make generally known the facts as to experiments on animals in this country, and the regulations under which they are conducted; the immense importance of such experiments to the welfare of mankind; and the great saving of human life and health which is already due to them. It is hoped that all candidates for Parliament, who may desire to acquaint themselves with these facts, will communicate with the hon. secretary, Research Defence Society, 70 Harley Street, W.

THE following appointments have been made at the National Physical Laboratory:—Dr. G. W. C. Kaye has been appointed an assistant in the metrology division. Dr. Kaye holds the degree of D.Sc. of London University, the B.A. research degree of Cambridge, and is an associate of the Royal College of Science and an associate member of the Institution of Electrical Engineers. He was formerly demonstrator in physics at the Royal College of Science, and a sub-lector in physics at Trinity College, Cambridge. Mr. Harris Booth has been appointed a junior assistant in the aëronautics division. Mr. Booth took the degree of B.A. at Cambridge, obtaining honours in mathematics and mechanical sciences. Mr. J. H. Hyde has been appointed a junior assistant in the aëronautics division. Mr. Hyde obtained in 1907 a Whitworth exhibition for engineering, and has had five years' experience at the works of the Great Eastern Railway Company.

SIR HENRY TRUEMAN WOOD, the secretary of the society, has edited a "Directory of the Royal Society of Arts," which has been published by Messrs. George Bell and Sons at the price of 2*s*. The pamphlet, which runs to seventy-six pages, contains a short sketch of the society's history, an account of the trust and prize funds which it administers, a history of the examinations which it has carried on for the past fifty years, a description and pictures of its medals, lists of the Albert medallists and of past and present officials, the charter and by-laws, and other general information, including a list of the proceedings of the past session, and a financial statement for the past year. The pamphlet provides abundant evidence of the honourable part taken by the Royal Society of Arts in the improvement and development of the scientific and technical education of the country. The work of the society is, and has been, at once scientific, technical, industrial, commercial, and artistic. For many years—for it must be remembered the society was founded in 1754—it alone filled the place which is now occupied by the numerous modern scientific and technical associations, the Royal Society and the Society of Antiquaries alone being in existence when the society was inaugurated. It was the Society of Arts that first directed public attention to the national need for technical education, and by its efforts aroused the public feeling which led to the appointment of the Royal Commission of 1881. The whole of the society's work has been carried on without Government aid, or, indeed, without any endowment. It is practically dependent entirely upon the annual subscriptions of its members. We welcome the new directory as likely to direct prominent attention to the excellent work the society is doing.

Dr. Francis Ward, who has been very successful in the photography of marine animals, described his methods, and showed the apparatus that he uses, at a recent lecture before the Royal Photographic Society. In a general sense, the apparatus is similar to the usual type of horizontal photomicrographic camera, but it is so hinged that the camera proper, including that portion of the baseboard that carries the microscope, can be raised into a vertical position. The microscope can be easily unclamped and removed, an ordinary photographic lens screwed into the flange of the camera, and the apparatus is then ready for photographing objects in horizontal or vertical tanks, 6 inches or 8 inches square. To facilitate manipulation the camera has an internal mirror and a hood, as in ordinary "reflex" cameras, so that focussing and adjustment may be done on either the horizontal or the vertical focussing screen. It is thus possible to work rapidly, and to adjust the apparatus in a very short time to the photography of specimens natural size or smaller, up to a magnification of about two thousand diameters. These high magnifications are obtained with a high-power projecting eye-piece and the longest camera extension—about 30 inches. For low magnifications, up to about twenty-five diameters, Dr. Ward prefers Zeiss's micro-planar lenses. By the use of a small arc-lamp as made for microscopic illumination, "instantaneous" work is possible, and Dr. Ward showed, by way of illustration, a photograph of living and moving oyster spat, magnified sixty diameters, taken in the tenth of a second. One special advantage of colour photographs, as on autochrome plates, was mentioned, namely, that specimens which will only take a quickly fugitive stain can be photographed while at their best, and so a permanent record obtained.

Alcyonarian and madreporarian corals from the Irish coast are discussed by Miss J. Stephens, of the Dublin Museum, in "Fisheries, Ireland, Sci. Invest., 1907, No. 5 (1909)," the paper including the description by Prof. Hickson of a new species of the genus Stachyodes.

Pictures of Arctic and Antarctic scenery, by Mr. F. W. Stokes, form some of the latest additions to the museums of the Brooklyn Institute. According to the December number of the *Museum News*, Mr. Stokes is absolutely the first to represent the scenery of the Antarctic in painting, while he has had but one predecessor in depicting that of the Arctic.

Among the additions to the Bristol Museum and Art Gallery recorded in the report for the year ending in September last are living specimens of Polypterus and Protopterus collected by the late Mr. J. S. Budgett, which have proved a source of interest to visitors. Numerous misprints of names, such as Myopotomus, *Procyon lator*, and Spizoetus, are apparent in the list of additions.

Naturen for December opens with a memoir and portrait of Mikal Heggelund Foslie, for many years conservator of the botanical collection at Trondhjem, who died on November 9, in the fifty-fourth year of his age. Prof. Foslie, who was well known in this country, devoted special attention to the calcareous algæ, of which he described the collection brought home by the Percy Sladen expedition to the Indian Ocean. In 1892 he paid a visit to the Isle of Wight for the purpose of collecting these organisms, and he also made a trip to Ireland seven years later with the same object.

We have hitherto omitted to mention that in the October number of the *American Naturalist* Miss Dederer comes to the conclusion, from a careful study of the skull and dentition, that the South American marsupials of the genus Cœnolestes appear to be more nearly related to the polyprotodonts than to the diprotodonts, among which they have hitherto been placed. In fact, the large pair of lower incisors, which may well be an adaptive feature, forms practically the only diprotodont character, the dentition in other respects being essentially polyprotodont.

To the *Field* of December 18 Mr. Douglas Carruthers communicates an article on the big game of Syria, Palestine, and the Sinaitic Peninsula, in regard to which our information has hitherto been defective. He adds the wild goat to the fauna of the district, and confirms Mr. Lydekker's statement as to the absence of the bubal hartebeest, the white oryx, and the addax. Particulars are given with regard to the horn-characters of *Gazella merrilli*, which is shown to be allied to *G. cuvieri* of the Atlas.

A correspondent of the *Yorkshire Weekly Post* of December 11 directs attention to the scheduling by the Westmorland County Council of the hawfinch as a protected bird. This he regards as a grave mistake, seeing that the hawfinch is one of the most mischievous birds against which the gardener has to contend. Reference is also made to the northern extension of the British range of this species, which was formerly unknown in Yorkshire. The writer also directs attention to the danger to birds caused by the ringing system, as it seems that specimens of various species are shot in order to ascertain whether or no their legs are ringed.

In the second and concluding part of his account of the life-history of the American toad, published in the December number of the *American Naturalist*, Mr. N. Miller asks the question why, in spite of the great fertility of the female, the numbers of the species remain practically stationary. Taking the low figure of 8000 eggs as the number in one spawn, it appears that with the exception of two, all these, as well as the whole of the eggs in the other spawns of the same female, must perish if the species remain, as appears to be the case, at the same numerical level. Various water animals, such as dragon-flies, water-beetles and water-bugs, together with their larvæ, newts, and crayfish, appear to be the chief agents in carrying on the work of destruction.

Great interest attaches to the description by Dr. E. L. Trouessart, in the October number of the *Annals and Magazine of Natural History*, of a new representative of the gymnuras, from Sze-chuen, for which the name *Neotetracus sinensis* is proposed. It will be remembered that until recently these remarkable Insectivora were known only by the Burmo-Malay genera Gymnura and Hylomys. A few years ago, however, a third genus, Podogymnura, was described on the evidence of a single specimen from Mount Abou, in the Philippines, and now comes the new Sze-chuen form, which is the smallest of all, and serves to connect the other Gymnurinæ with the Erenaceinæ. It has, in fact, the general appearance of Podogymnura coupled with the dentition of a hedgehog. The genus has been named from the apparent resemblance of the lower jaw to the one from the French Miocene on which was founded the genus Tetracus.

In the *Journal of Hygiene* for November (ix., No. 3) Prof. Hewlett, Mr. Villar, and Mr. Revis discuss the nature of the cellular elements present in milk. They conclude that the majority are not leucocytes, as has generally been supposed, but are derived from the secreting epithelium of the udder. Moreover, vast numbers of these cells may occur in the milk of perfectly healthy cows. Some have considered that these cells (so-called leucocytes or pus-cells), when present in any number, indicate inflammation and suppuration of the udder, but in view of this work such a conclusion does not appear justifiable.

THE growing interest in India among Americans is shown by the fact that the *National Geographic Magazine* for November is largely devoted to a series of excellent photographs illustrating the temples, tombs, and people of the country, by Mr. W. M. Zumbro. It is unfortunate, however, that the titles of the plates and the letterpress were not submitted to the revision of someone more familiar with Indian life and architecture.

"TIDE Tables for the Eastern Coasts of Canada for the Year 1910," by Dr. W. Bell Dawson, have been issued by the Tidal and Current Survey in the Department of Marine and Fisheries, Ottawa. The tables are based upon observations obtained by means of self-registering tide-gauges kept in continuous operation, and, owing to the length of the series of observations, can lay claim to considerable accuracy. The records are reduced by the latest methods of analysis, by which the tidal constants are arrived at, and from these the tables are calculated by the Nautical Almanac Office in London. The paper also includes useful summaries of the more important results of investigations regarding the currents in various regions contained in the reports issued by the Survey; copies of these full reports, illustrated by charts and plates, may be had on application to the department.

A REPORT on the rainfall of the Exe Valley, by Dr. H. R. Mill, forming part of the report of progress in the investigation of rivers, by Dr. A. Strahan and others, is contained in the *Geographical Journal* for December. Owing to the scarcity of long records, Dr. Mill found it necessary to construct maps for four decades between 1868 and 1907 from the data which are summarised in the tables, and to combine these four maps into one of forty years' average by a somewhat laborious process, fully explained in the paper. This map shows that the heaviest rainfall occurs on Dartmoor, where a wide area has more than 70 inches per annum, but that this amount diminishes rapidly in all directions. The general rainfall of the whole of the Exe Valley is shown to be about 42 inches, and nowhere less than 30 inches. Roughly speaking, the Culm and Creedy receive an equal volume of rainfall over their basins, and the Exe three times as much as either. The four ten-year groups of the mean annual rainfall over the whole area show 107, 103, 95, and 95 per cent. of the average; with regard to this, Dr. Mill remarks that he sees no reason for supposing that there is a progressive diminution of the annual amount, though a comparatively dry spell has succeeded a comparatively wet one.

THE geological section of the Belfast Naturalists' Field Club held its first meeting of the winter session on November 24, when one of the members, Mr. James Strachan, delivered a lecture on petrological types of basalt in County Antrim. The chief portion of the lecture was devoted to a suggested rational classification of the basaltic rocks of Co. Antrim according to their varying basicity. Three main classes were recognised, and subdivided as follows:—(1) Basalts without olivine (basaltic andesites): (*a*) flow type, basalt of Spanish Bay, Giant's Causeway; (*b*) intrusive type, dolerite of the Neck at Carnmoney Hill. (2) Olivine basalts: (*a*) flow type, the common olivine-basalt of the district, with olivine increasing from occasional grains to plentiful porphyritic crystals; (*b*) intrusive type, the common olivine-dolerite of the district with varying amount of olivine, *e.g.* dolerite of the Neck at Scawt Hill, and that of Ballygalley Head. (3) Basalts rich in olivine: (*a*) flow type, containing excess of olivine in large phenocrysts, minimum of felspar and augite and colourless interstitial glass; north side of Carnmoney Hill; (*b*) intrusive type, dolerite rich in olivine; Slieve Mish. These types of basaltic rocks were all illustrated by hand-specimens and numerous microscopic sections. In conclusion, the lecturer referred to several peculiar features of the local basalts, such as the fairly common occurrence of "tube-amygdaloid" at the basal portion of many of the Co. Antrim flows, and the complete inclusion of primary minerals, such as felspar and augite, in natrolite and other zeolites.

THE Bausch and Lomb Optical Company, 19 Thavies Inn, E.C., have submitted an improved Störmer viscosimeter for our inspection. In this apparatus a weight falling from rest causes a paddle to rotate in the oil or other liquid to be tested, and a dial registers the number of revolutions made. The time required for a given number of rotations is taken with a stop-watch; it varies with the viscosity of the liquid. Thus, when the apparatus is so adjusted that 100 revolutions in water take 12 seconds, with ether the time is 9·8 seconds, and with glycerine 36·8. The viscosities are reckoned as proportional to the time, that of water being taken as unity. To obviate "spinning" of the liquid a square receptacle is used. Some of the advantages claimed over other types of apparatus are:—(1) Only a small volume of liquid (50 c.c.) is necessary; (2) a determination is made in a few seconds, and can be easily repeated upon the same identical quantity of liquid; (3) the variation due to change of temperature during the operation is practically negligible, since the time is so short; and (4) given spare cups, a series of tests can be made without any waste of time in cleaning the instrument after each experiment. The apparatus is compact, and appears quite easy to manipulate.

THE *Verhandlungen der deutschen physikalischen Gesellschaft* for November 15 contains a critical examination, by Dr. Karl Kurz, of the theories which have been advanced to account for the existence of the penetrating radiation of the nature of γ rays in the atmosphere, and even in vessels hermetically sealed. There are three possible sources of this radiation. It must come either from an extra-terrestrial source, from the earth's atmosphere, or from the material of the earth itself. The author shows that the extra-terrestrial source must be excluded, owing to its leading to consequences in the upper atmosphere which are not in agreement with observations. The atmospheric source he shows to be quite inadequate, the quantity of radio-active matter present being much too small. The radio-active matter present in the soil is, however, not only sufficient to account for the radiation, but gives its intensity correctly as that necessary to produce nine or ten ions per cubic centimetre per second. The semi-diurnal period observed in the amount of radiation the author ascribes to the radio-active matter present in the atmosphere.

THE belief that areas of seismic and volcanic activity move slowly to the west is given a precise form in a paper, by Mr. H. Wehner, which appears in the *Physikalische Zeitschrift* for December 1. He assumes that within the solid crust of the earth, and separated from it by a thin layer of liquid, is a solid nucleus which rotates about the same axis as the outer shell and in the same direction, but with a velocity slightly less than that of the shell, the result being that, with respect to the shell, the nucleus makes one revolution to the west in 952 years. On this revolving nucleus the author assumes there are projecting or "active" spots which in their motion come under weak portions of the crust and cause earthquakes and volcanic disturbances. On this basis he calculates the positions of the active spots on the nucleus which have during the last sixty years produced disturbances notified by ships at sea in the tropical parts of the Atlantic. According to the calculation, these active spots are now nearly all collected under the region between longitude 35° and 41° W., and latitude 1° N. and 1° S., which should therefore be a danger zone. It will be interesting to see if further statistics support this theory.

We have received from Lu-kia-pang, China—which now serves as the magnetic observatory of the Jesuit fathers of Zi-ka-wei—an interesting copy of the record of the great magnetic storm of September 25, with some notes thereon. The storm in China was of similar duration to that experienced in this country, and presented many similar features, but the oscillations were of a much less striking character. The ranges of the declination and vertical force disturbances—about 50′ and 0·002 C.G.S. respectively—were much less than in Europe. The range in horizontal force, however, exceeded 0·005 C.G.S., and the excess may have been large, as the trace was off the sheet during the greater part of the storm. About three hours before the large disturbance began there was a curious little movement, seen in all the elements, which is described in the "Notes" as a precursor of the storm. We understand that movements corresponding to the supposed precursor are distinctly shown on the Kew curves, so that whether related or not to the great storm they seem to have been, like it, experienced all over the world.

The dissociation of hydrobromic and hydriodic acids at high temperatures is the subject of a paper by K. V. v. Falckenstein in the current number of the *Zeitschrift für physikalische Chemie*. The method used is the statical one, first employed by Löwenstein, and is based on the fact that at a high temperature platinum permits the passage of hydrogen, but of no other gas. The action of the red-hot metal may be roughly regarded as a filter, the pores of which are so small that only the very small hydrogen molecules can pass through. The gaseous hydrogen compound, contained in a fused quartz tube and heated in an electric resistance furnace, passes over a platinum bulb, the inside of the latter being connected to a manometer. The pressure of the hydrogen inside the bulb is in equilibrium with the hydrogen outside the bulb arising from the dissociation. Data are given for three temperatures, 1024°, 1108°, and 1222°, in the case of hydrobromic acid, and for two, 1022° and 1217°, for hydriodic acid. Bodenstein and Geiger have measured the E.M.F. at 30° of the cell Br_2—HBr—H_2, and Haber has deduced a formula for the relation between the amount of dissociation of the hydrobromic acid and the temperature. It is interesting to note that the dissociation calculated from this formula, in spite of the large temperature difference between 30° and 1200°, is in very fair agreement with the experimental results described in this paper.

The sixty-sixth annual issue of the Medical Directory, for 1910, published by Messrs. J. and A. Churchill (price 14*s*. net), includes several new features. It appears from the numerical summary that there are 40,558 members of the medical profession, the increase from 1909 to 1910 being 566. The directory includes, for the first time, a section on the principal British spas and climatic health resorts, by Mr. N. H. Forbes. Improvements have also been made in the list of hospitals and other institutions printed at the end of the London section of the directory.

Messrs. Charles Griffin and Co., Ltd., have published a sixth edition of Prof. Grenville A. J. Cole's "Aids in Practical Geology." Alterations have been made in more than a hundred places, and the subject-matter has in this way been brought up to date. While certain modern restrictions in nomenclature have been introduced, the limits of the names of rocks and fossil genera have, as in previous editions, been kept as wide as possible. Prof. Cole's book has been of signal service to very many practical geologists since its first publication in 1890, and in its latest revised form we have no doubt its sphere of usefulness will be extended.

OUR ASTRONOMICAL COLUMN.

Halley's Comet, 1909*c*.—As was briefly stated on p. 239 of our issue of last week, M. Deslandres has added to the large reflector at Meudon a finder, fitted with a moving reticle, which enables the instrument to be used for photographing any faint object moving in relation to the surrounding guiding stars. The aperture of the large reflector is 1 metre, the focal length 3 metres, and an exposure of five minutes, on December 6, 7, and 8, was sufficient to give a sharp image of the comet's central portion. With an hour's exposure the comet was seen, on the negative, as a nebulosity, elongated in the direction opposed to the sun. The finder now in use has an aperture of 15 cm. (6 inches) and a focal length of 2·3 metres, and may be placed on either side of the telescope to suit the convenience of the observer, a suitable counterpoise of the same form being employed on the opposite side.

In conjunction with M. Bernard, M. Deslandres also describes two spectra of the comet secured on December 6 and 8 with exposures of two hours and three hours respectively. That the comet, on December 6, was already emitting its own radiations is shown by the appearance of bright condensations at λ 388 and λ 391·45, as in Morehouse's comet last year. In addition to the nearly circular nucleus, several curved rays, fainter than the nucleus and having the appearance of antennæ, were seen; from their direction it is difficult to account for these rays solely on the assumption that they are produced by solar repulsion. A spectrum taken on December 13 shows the continuous spectrum of the nucleus stronger and the condensations in the ultra-violet larger, the latter radiations evidently emanating from the nebulosity surrounding the nucleus. There is also some evidence for the oscillations of brightness observed at Greenwich (*Comptes rendus*, No. 24, December 13).

Other visual observations of the comet are recorded in No. 4377 of the *Astronomische Nachrichten*, where Prof. A. A. Iwanow also has a paper describing his calculations of the perturbations of the comet's path between 1835 and 1910. His final elements give April 23, 1910, as the probable date of perihelion passage.

An Interesting Sun-spot.—In No. 4377 of the *Astronomische Nachrichten* M. Amaftounsky describes the changes in detail which took place in a sun-spot first seen on the sun's eastern limb on September 27 (September 15 O.S.). Six drawings which accompany the paper show how enormous were the changes, and M. Amaftounsky directs special attention to a marked yellowish-green tint which pervaded the bright tongues, or bridges, over the nucleus and the bright edges of the penumbra. This was not an optical coloration, and, according to the observer, is a very rare phenomenon.

Periods in the Variation of Latitude.—No. 8 of the *Bulletin International de l'Académie des Sciences de Cracovie* (October, p. 543) contains a *résumé*, in French, of a memoir by M. Jan Krassowski, in which the author briefly discusses the results obtained by him in an analysis, by Schuster's "periodogram" method, of the motion of the pole. The data employed consisted of all the results published by the International Latitude Service since 1908. Periods of one-fortieth of a year (9·125 days) were taken, and the values for x and y analysed independently, special attention being paid to the possible demonstration of a yearly period.

The resulting maxima show no trace of an annual period, but there is a weak maximum at thirteen months. A very strongly marked period, of 419·750 days for the x, and 410·625 days for the y, coordinate, was found, and agrees fairly well with the period (428 days) found by Chandler. Another less marked period of 438·0 days also results from M. Krassowski's investigation, and agrees with that found by Mr. Kimura.

THE PLANET VENUS.—In a very interesting lecture, now published in the December number of the *Popular Science Monthly* (vol. lxxv., No. 6, p. 521), Prof. Lowell describes the observations which have been made of the planet Venus, at present so prominent an object in our evening skies. Not only are the observations described, but the results accruing from them are discussed in popular language. Thus the spectroscopic and visual observations are held to have proved that the rotation and revolution of Venus are synchronous, the period being 225 days. A number of drawings accompanying the paper show the permanent markings recorded, and illustrate the unanimity of the observers working under good conditions. The main feature is a number of dark markings which, leaving the limb at different points, converge to the centre, thus giving the planet's disc a cart-wheel appearance.

SUGGESTED OBSERVATIONS OF HALLEY'S COMET.

THE Astronomical and Astrophysical Society of America, through its comet committee, is soliciting cooperation in the observation of Halley's comet at the present return, and has prepared a circular letter of advice that has been widely distributed among observatories with regard to such observations. A copy of this circular will be sent to any astronomer who may desire to use it upon request being made to the chairman of the committee, Prof. G. C. Comstock, Washburn Observatory, Madison, Wisconsin. As many astronomers and other observers of Halley's comet will be interested in the suggestion made by the committee, the circular is here reprinted in a slightly abridged form.

It is desirable that the position of the comet be well observed during the entire period of its visibility, and it seems probable that extra-meridian observations will be secured in sufficient number without especial solicitation. In view, however, of possible large perturbations arising from the close approach of the comet to Venus on May 1, and to the earth on May 18, meridian observations are especially desired during the period in which the comet is sufficiently bright for that purpose. An examination of the amount and character of these comet perturbations and their adaptability to a determination of the mass of the planets producing them has been undertaken by Profs. Leuschner and Crawford, and in case the conditions prove favourable, the meridian determinations may well be supplemented by heliometer observations of the positions of the inner planets with the view of a possible determination of the mass of the comet itself.

The close approach of the comet to the earth promises unusual opportunity for a study of the physical conditions that obtain in such a body, and, as an indispensable basis for such study, the committee recommends a photographic campaign as long and as nearly continuous as possible. The comet's close proximity to the sun's direction at the time of maximum brilliance imposes serious limitations upon this programme, and widely extended cooperation will be required throughout the whole circuit of the earth if this ideal of a continuous photographic record is to be even remotely realised.

About one-third of the earth's circumference in longitude is covered by the Pacific Ocean, within which there is known to exist no observatory with proper facilities for celestial photography. To fill this gap, at least partially, the committee, aided by a grant from the National Academy of Sciences, proposes to send to the Hawaiian Islands an expedition to photograph the comet during the period of its greatest brilliance.

The ends to be served by these photographs, and others obtained elsewhere, are as follows:—

To give a permanent record, as continuous as possible, of the phenomena and changes (1) in the tail of the comet, with special reference to outgoing masses; (2) in the head and nucleus of the comet, particularly as to the formation of envelopes and jets.

The following suggestions as to procedure and precaution in making the photographs have been formulated by Prof. Barnard.

Photography of Comets.

One of the greatest difficulties in photographing the average bright comet is its proximity to the horizon, and consequent projection on a more or less dawn or twilight sky. The effect of this illuminated background with any considerable exposure is to fog the plate to such an extent as either to ruin it or to prevent a proper development of the image of the comet. A difference of three or four minutes in the duration of exposure when the sky is brightest may make a success or a failure of the picture. It is impossible to establish fixed rules as to when the exposure should stop or begin; so much will depend upon the condition of the sky, the position of the comet, the kind of lens, the rapidity of the plates, &c. The best rule is that of the judgment of the observer at the time, and this can only be derived from actual experience in the work.

The plates should be backed with the following to prevent halation. Cook two pounds of white sugar in a saucepan without water until nearly in the caramel stage, then add one pound of burnt sienna. Cook a little more (but not to the candy stage), stirring well. Finally, add about one-half an ounce of alcohol to each pint of backing as a dryer. This backing will keep indefinitely. When it is too hard, moisten it with a little water. This is to be applied to the back of the plate as a stiff paste with a broad camel's-hair brush, and should be applied just before using. A piece of old newspaper pressed upon this will prevent its being rubbed. The face of the plate should be very carefully dusted with a broad camel's-hair brush after it has been placed in the plate-holder. The camera tube should also be frequently wiped out with a damp cloth to avoid dust. Before developing, remove the backing with moist absorbent cotton. If a little remains on the plate it will not injure the developer. In removing the backing be careful to shield the plate from the dark-room light. Do not wet the surface of the plate before pouring on the developer, as it may cause air bubbles on the film; swab it carefully with absorbent cotton at the beginning of development. Develop until the plate is almost opaque to the ordinary developing light. Fix for twenty minutes or more in the ordinary fixing bath (frequently made new), to which has been added a teaspoonful of sodium bisulphite to prevent discoloration.

Lumière Sigma dry plates are recommended, because of their rapidity. Seed 27 Gilt Edge and Cramer Crown are both beautiful plates, but are not now so rapid as the Sigma.

Hydrochinon developer gives a good strong negative, and for astronomical work is excellent. Rodinal in a weakened form, say 1/60 or 1/70 of water, with a longer development, will give a soft and more transparent negative, especially suited for showing the details of the head of the comet on large-scale photographs.

The doublet, or portrait lens, such as is made in America by the Brashear Optical Company and the Alvan Clark Corporation, on account of its wide field, is the best form of instrument for showing the general features of the comet and its tail, and especially for following any outgoing masses that may appear in the tail. One of about 6 inches (15 cm.) aperture will be the most generally used, because of the expense of such instruments. It should be supplemented by several smaller lenses. A "lantern" lens of 1½ inches (4 cm.) aperture and about 6 inches (15 cm.) focus, made by McAllister, of New York, is recommended for showing the extent of the tail. The cost of one of these lantern lenses is seven dollars. It gives a good field of twenty to thirty degrees, especially when diaphragmed down to 1 inch. It is extremely quick for comet work. Its focus should be carefully determined by star trails.

In comet work it is important in all these lenses that the camera should be so adjusted on the mounting with respect to the guiding telescope that the head of the comet can be displaced to one side of the field to secure a greater extension of the tail. Two of the small lenses may be so arranged by a mutual adjustment as to cover the full length of the tail, even though it should be fifty degrees long or more. Although it would thus be in two sections—the head and part of the tail on one plate, and the rest of the tail on the other—there would be no serious objection if the whole tail could thus be secured. The large reflectors will be of the utmost importance in dealing with the detail and structure of the head and envelopes, as has been recently shown at Greenwich.

Until something further is known of the spectrum of the comet, it would be unwise to attempt to give any specific directions as to the duration of exposure required with any telescope. Daniel's comet of 1907, and Morehouse's of 1908, were very different in respect to their photographic activity. The latter was relatively many times more actinic in its light, and hence required much shorter exposures to show the same strength of tail. This information must come from actual experience with the comet. It would seem, however, that the circumstances of the comet's visibility when brightest will make short exposures necessary.

The committee will be pleased to receive from every astronomer who may cooperate in the matter copies (glass positives) of his negatives of Halley's comet, and it will undertake the comparison and discussion of the material thus collected.

Spectroscopic Observations.

For spectroscopic observations of the comet the committee makes the following suggestions, formulated by Prof. Frost. While it may be possible to make visual observations of the comet's spectrum with ocular spectroscopes attached to large telescopes, it is likely that most of the photographic records of the spectrum will be obtained by the objective prism or the slit spectrograph, and reference will be made in what follows to the use of these two types of instrument.

These methods of observation are mutually complementary; for the accurate measurement of wave-length, effect of motion in the line of sight, and analysis of structure of lines or bands (if sufficiently sharp), the slit spectrograph has all the advantages, but for study of distribution of elements in different parts of the comet, and for reaching faint details, the prismatic camera, or objective prism, with its much greater light-power, is essential. The prismatic camera may be employed, with a fair possibility of success, when the comet's brightness is equivalent to that of a ninth- or tenth-magnitude star; the slit spectrograph cannot be hopefully applied before the comet is two or three magnitudes brighter. The size and kind of telescope employed, of course, make such statements relative rather than absolute, and uncertain at best. Too much here depends upon the comet; if its light is chiefly reflected rather than intrinsic, and the continuous spectrum is predominant, then the comet will have to be much brighter for satisfactory spectroscopic analysis than if the light is largely intrinsic and concentrated at half a dozen points in the spectrum. Comets showing sudden and marked fluctuation in size or brightness are likely to exhibit changes in the bright band spectrum.

(1) Prismatic camera or objective prism.

The camera should be a doublet of large angular aperture, 1/4 or 1/5. Useful observations could be secured if the linear aperture is as small as 4 or 5 inches (10 or 12 cm.). The objective prism should be of small angle, perhaps 10° or 15°; if an additional prism is available for the period of the comet's greatest brightness, its angle should be about three times that of the smaller prism. If the doublet is of comparatively short focus, as is likely to be the case, it will be found to be quite sensitive to focus, and separate exposures will be needed for the blue-violet region and the yellow-green region. Optical parts transparent to ultra-violet would be useful, as there may be some important bands of shorter wave-length than λ 3883.

It is very desirable to photograph the spectrum of a star before or after the comet, placing the star at such a point on the reticle of the guiding telescope that the stellar lines may serve for comparison.

Prof. Pickering suggests that an interesting observation would be to photograph the spectrum of a star when seen through the bright portion of the tail, to see if dark absorption lines could be detected.

(2) Slit spectrograph.

A small spectrograph will be a very useful attachment to a photographic doublet as described above. It need not be complicated, and its dispersion may be small. Apparatus for producing a comparison spectrum is not essential, for a neighbouring star of the first type may be brought upon the slit, and its spectrum impressed above and below that of the comet. With one thread of the guiding telescope, or finder, movable, the star can be placed so that its spectrum will fall on the slit as desired. The identity of the cometary band can be thus established better than with the objective prism. After spectrograms of the comet have thus been obtained, it will also be desirable to obtain plates with the slit as narrow as feasible, in order to detect duplicity or complexity of the lines or bands.

Observations with powerful stellar spectrographs of the types in use for determining radial velocities will doubtless be made as soon as the comet's brightness permits, but this is likely to be disappointingly late on account of the heavy loss of light in such instruments. The fixed equipment of these instruments will determine their operation by their regular observers.

Photometric and Polariscopic Observations.

Photometric and polariscopic observations of the comet should certainly be made, although they will doubtless occupy a position of subordinate importance. The suggestions of the committee in this respect are formulated by Prof. Pickering, as follows:—

A great variety of methods may be employed for measuring the light or amount of polarisation of the comet. It is suggested that astronomers undertaking this problem should correspond with the chairman of the committee, in order that uniform methods may be employed throughout by different observers. The plans proposed below may require modification, according to the instruments available.

A direct estimate, by Argelander's method, of the entire light of the comet, as seen by the naked eye, or in the smallest telescope with which it is visible, may have a certain value to observers in the future, although large systematic errors are to be expected in such estimates.

It is doubtful if photometric measures of the nucleus of the comet will have much value, as the results will probably be greatly affected by the coma, and will differ with different photometers and telescopes. If the nucleus be distinctly stellar it may be compared directly with an adjacent star, by means of a double-image photometer. The effect of background would thus be eliminated. Direct measures with a Zöllner photometer, or similar instrument, would probably have but little value, owing to the effect of the coma. Any series by the same observer with the same instrument would be valuable by itself, and the observations by different persons and different instruments might be subsequently adjusted for systematic differences.

The measures described in Harvard Circular 68 showed that the absorption of light by the tail of comet 1902*b* was certainly less than a tenth of a magnitude. Similar measures should be made of Halley's comet. A double-image photometer is indispensable for these measures also, to eliminate the effect of background.

The light of different portions of the tail of the comet may best be measured by the following method. Take two photographs at the same time with similar instruments, using the same kind of plate and developer, and giving equal exposures, taking one in focus and the other out of focus, so that the images of the stars shall appear as circles two or three millimetres in diameter. Make similar enlargements of the two plates, interposing screens of perforated brass. Measures of the opacity of the resulting circular images of different portions of the comet on one plate may be compared with the images of stars the magnitudes of which are known as photographed on the other plate. The effect of the light of the sky or of twilight may thus be eliminated, and the light of the comet compared with that of a star of known magnitude spread over a standard area. The two photographs may also be compared directly with a suitable photometer.

Messrs. Barnard and Frost, having also the benefit of Mr. Parkhurst's opinion, suggest as an alternative and possibly better method the extra focal use of a single camera. The intensity of the extra-focal cometary image could be reduced to the focal plane as accurately as for the star images. The relative values on different nights would always be correct.

Useful suggestions for the photometric observations of the comet may be derived from a paper by Dr. Rosenberg upon photometric observations of the Morehouse comet, contained in the *Astrophysical Journal* for November.

The polarisation, if any, of the comet's tail may best be studied by photographs taken with a camera having a double-image prism placed over the lens. The prism should be turned so that the two images are perpendicular to the direction of the sun. The two images of an unpolarised object should be alike if the correction for colour is the same for both, otherwise it will be necessary to take a second photograph, turning the prism 180°. If the light is polarised, one image may be fainter than the other, as in similar photographs of the solar corona. Measures may be made as described in the preceding paragraph.

Bands will doubtless be seen if the comet is examined by means of a Savart's polariscope or similar instrument, but it is, in that case, difficult to distinguish between slight polarisation of the comet and the strong polarisation of faint sky-light.

Minor Notes.

The following titles may be specified as minor matters not included above, but which may in some circumstances become of importance, viz. :—

The head of the comet should be carefully examined for traces of phase. Possible disturbances may be found in the comet, due to its close approach to Venus on May 1 and to the earth on May 18. A transit of the earth through the comet's tail is possible at or near the latter date, and, if such should occur, a meteoric shower should be looked for and observed with reference to a determination of the meteoritic particles, their frequence, size, &c. Resultant disturbances of the electric potential of the earth's atmosphere are possible, and the cooperation of meteorological observers, and especially of national weather bureaus, is earnestly desired in this connection.

Although the amount of refraction experienced by light in transit through a comet is known to be very small, it seems desirable to make investigation of the matter photographically with long-focus telescopes. The position of a sufficiently bright star near the nucleus, or in the brightest part of the edge of the tail, should be referred to a group of more distant ones, and the resulting position of the star compared with that resulting from another plate exposed after the comet has left the star.

THE HEADMASTERS' CONFERENCE.

THE headmasters of sixty of the leading public schools met at the Leys School, Cambridge, on December 22 and 23. On the first day the chief matter discussed was the work of the Public Schools' League for Imperial Land Settlement in the Overseas Dominions, which was strongly supported by the Rev. Dr. Gray (warden of Bradfield College). Under the auspices of the committee, approved boys are to be sent to a Canadian farm after completing their school career. A course at an agricultural college is to follow a year's practical training on the farm, and it is hoped that the public schools will assist the supply to the dominion of "men of character, intelligence, and energy, possessed of a little capital, who will settle down seriously and will assist in bringing under cultivation the immense areas of land at present untouched." The conference pledged its support to the establishment of a central office in London for the permanent work of the league. Later in the day the meeting asked for fuller recognition of English in the university examinations for admission. All the speakers emphasised the importance of the subject, which was no longer regarded as something for a spare hour; not a few were of opinion that to add English to the entrance examinations would be the worst service they could do to the cause. Fear was expressed lest a set period or figure in literature might be made compulsory, and the comments of some speakers upon the university examinations were decidedly caustic.

On the second day the meeting debated the report of the curriculum committee as to a scheme of studies for schoolboys from the age of nine to about sixteen. The conference passed, practically unanimously, the three following resolutions :—

That this conference approves the principle laid down in the curriculum report of the committee that a boy should not be allowed to begin Greek until the foundations of Latin and French have been securely laid and he has received systematic training in English.

That it is essential to give such a definite position to English and French in the entrance scholarship examinations that these subjects may not be sacrificed to a premature study of Greek; that this meeting be urged to take such steps as will ensure full consideration of the nature and results of the mathematical teaching of boys from nine to sixteen; and that it be referred to a subcommittee to consider and report to this meeting.

That a special meeting of those headmasters who are in favour of the recommendations of the committee be summoned in the early part of next year to take steps to give practical effect in their own schools to the proposals made by the committee, and with this object in view that the secretary be instructed to send a circular to the members of the conference in the third week of January asking whether they are generally in favour of the recommendations of the committee, and, if so, whether they will be prepared to meet in London on a certain date in February or March.

There were several points in the report which were not dealt with in the resolutions, *e.g.* the committee is convinced that German should be excluded from the preparatory school. At the present time the two languages must be Latin and French, in order to provide a basis of education preparatory to classical and modern sides. Dealing with mathematics, the committee reports that in some cases the attempt is made to cover too much ground for the average boy, yet in others there is a danger that mathematics may be sacrificed entirely.

Although reformers will wish that the headmasters had gone further, it is a matter for congratulation that this year's conference exhibited a progressive spirit alike in resolutions and in individual speeches. Not only did the meeting recognise the relation of the public schools to the Empire, but it deprecated early specialisation in Greek, encouraged the advance of English studies, and adopted the principle of differentiating curricula to suit varying capacity. Above all, the headmasters acknowledged the obligation to give practical effect to the opinions which they expressed in conference. Perhaps we may not have to wait many years before drawing, nature-study, music, and handwork are accorded the status of essential subjects in the preparatory curriculum. G. F. D.

WATER SUPPLY IN THE UNITED STATES.[1]

IT is an obvious truism that water is the commonest and most plentiful substance in nature. Oceans, seas, lakes, rivers, floods, and streams innumerable testify to its universality, and its indispensability is no less manifest. Whenever man penetrates into virgin territory, his first care is to find water; wherever civilisation sets up her ultimate standard of health and comfort, she establishes and secures an efficient water supply. Water is the embodiment of all that is delightful in art, useful in industry, valuable to commerce, and essential to existence.

---

[1] Water Supply Papers: No. 224 Some Desert Watering Places in South-eastern California and South-western Nevada. By Walter C. Mendenhall. Pp. 98.

No. 228. Water Supply Investigations in the Yukon-Tanana Region, Alaska, 1907 and 1908. By C. C. Covert and C. E. Ellsworth. Pp. 108.

No. 230. Surface Water Supply of Nebraska. By J. C. Stevens. Pp. 251.

No. 231. Geology and Water Resources of the Harvey Basin Region, Oregon. By Gerald A. Waring. Pp. 03.

No. 224. Papers on the Conservation of Water Resources. Pp. 96. (United States Geological Survey. Washington: Government Printing Office 1909)

Hence the interest attaching to these publications of the United States Geological Survey, dry (paradoxical term!), statistical records for the most part, but none the less engrossing in their importance, and even entertaining at not infrequent intervals. Amid a voluminous mass of data, carefully and patiently collected from day to day and year to year, it is surely worthy a passing glance to note that the mean annual rainfall over the United States is 29·4 inches, that the heaviest precipitation occurs upon the North Pacific Coast, where, at several points in the States of Washington and Oregon, it exceeds 100 inches, while at the back of the coastal mountain ranges the rainfall diminishes rapidly southward, so that in the State of Nevada it ceases altogether, or is negligibly small. From another paper comes corroborative evidence on the value of afforestation, in that the data obtained clearly demonstrate the fact that an increase in floods is directly associated with the denudation of forest areas. Again, it is of considerable industrial importance to have an estimate of the total available water horse-power throughout the country. This is stated to lie between 200 and 250 millions, of which only $5\frac{1}{2}$ millions have as yet been utilised. Yet again, from a geological point of view it is instructive to learn that the whole surface of the United States is being denuded at the rate of 1 inch in 760 years, representing an annual transportation of 270 million tons of dissolved matter and 513 million tons of suspended matter to tidal waters.

But the volumes are not merely academically and statistically interesting. They have a human side, which at times is forcible in its suggestiveness. Here and there are touches of the grim reality of things, allusions at once startling and tragic, pictures which bring us face to face with the deadly antagonism to humankind of nature in her more savage aspects. Take, for instance, the pamphlet entitled "Some Desert Watering Places in California and Nebraska." Here are no descriptions of well-watered plains and fertile valleys, but vivid sketches of an arid, desolate region, comprising an area of 68,000 square miles, where "the scarcity of water and the importance of a knowledge of its whereabouts are indicated by the frequency with which the Press records instances of death from thirst in the more remote parts of the desert." The Death Valley region comprises plains which are absolute deserts, totally destitute of water and treeless for a space representing many days' journey. The following extract, under the head of "Getting Lost," gives a vivid sketch of the possibilities of a desert tragedy:—

Death Valley, looking north toward the Black Mountains.

"The inexperienced traveller often gets at once into a panic on losing his way, and wastes his remaining energy in frantic rushes in one direction and another. This tendency to become panic-stricken should be controlled, if possible. Sit down, get out your map and compass—if you are provided with them, as you should be—and study the situation carefully before acting. At least, rest a little and think it over. If it is hot and you are far from camp, get your head into the shade of a bush or rock, and wait till night. Thirst will be less intolerable then and endurance greater. If you have camp companions who are likely to look for you, start a signal fire by night or a smoke by day from some little eminence, and then stay by it till help comes. If you must depend on your own exertions, think carefully over all the possibilities and adopt a plan of action and adhere to it."

Excellent advice! but it is one thing to read it amid the bustle of a crowded city and another to act upon it in the lonely and fearful silence of the illimitable desert.

B. C.

SOME RECENT WORK ON TROPICAL MEDICINE.

TWO recent numbers of the *Annals of Tropical Medicine and Parasitology* (vol. iii., No. 2, October 20, and No. 3, November 1) contain six memoirs, of which four deal with problems relating to trypanosomes and the diseases caused by them. Messrs. Kinghorn and Montgomery discuss the important and difficult question of the flagellates found in the intestine and proboscis of tsetse-flies caught wild, on the basis of observations made by them during their expedition to the Zambezi, 1907–9. In *Glossina palpalis* collected by them on Matondwi Island, at the southern extremity of Lake Tanganyika, an island that has been uninhabited for twenty years, they found, out of 185 flies dissected, no fewer than seventy-eight, or 42·1 per cent., harbouring flagellates in the intestine, a percentage which far surpasses all previous records from other places; no parasites were found, however, in the proboscis. In *Glossina morsitans* collected near Kambole, about fifty miles west of Abercorn, nine out of 113 flies examined, or 7·8 per cent., were found infected with flagellates in the intestine, and seven out of thirty-one flies examined, or 21·2 per cent., were found to contain flagellates in the proboscis.

The authors give a detailed description of the parasites, but, unfortunately, without any figures; they consider that the flagellates observed in *G. palpalis* are to be referred to the type of *Trypanosoma grayi*, Novy, but they did not observe the encystment described by Minchin. The parasites observed in *G. morsitans* only differed slightly from those observed in *G. palpalis*. Feeding experiments were undertaken in order to trace, if possible, a development of the flagellates found in *G. palpalis*, and with rather surprising results, for while 42 per cent. of flies not fed artificially contained trypanosomes, in those fed only a very small proportion were found to harbour these parasites. It was also found that the percentage of intestinal infections tended to decrease when flies were kept in captivity, while, on the other hand, the percentage of infections of the proboscis tended to increase; but the number of cases examined is scarcely sufficient to support these conclusions.

The origin of the trypanosomes occurring in "wild" tsetse-flies is discussed, but without reaching very definite conclusions. The authors agree with Stuhlmann that the parasites in the proboscis are derived from those in the intestine, and they suggest the possibility that the trypanosomes found in "wild" tsetses "may be derived from pathogenic trypanosomes which lose for some unknown reason their infectivity when ingested," and also that they represent a mixed infection.

In two other memoirs the same authors report at length on human trypanosomiasis in north-eastern Rhodesia and Nyasaland, and on trypanosomiasis of domestic stock in north-eastern Rhodesia. The reports contain much valuable information concerning the habits and occurrence of the species of Glossina and other biting flies, the various types of trypanosomes (illustrated by photomicrographs) met with in the blood of diseased domestic animals, and other important points, and the question of prophylactic measures against trypanosomiasis is discussed both for human beings and animals.

In another memoir Messrs. Breinl and Nierenstein give an account of their biochemical and therapeutical studies on trypanosomiasis. After a detailed account of their "observations on experimental trypanosomiasis, the treatment of infections with different pathogenic trypanosomes, and the mechanism of the therapeutical action of various trypanocidal compounds," they raise the question, "When can an animal be considered to be cured?" No very definite answer is given, however, to this question, and it is concluded that "the general condition of experimental animals influences to a large extent the results obtained in therapeutical experiments." The memoir ends with a brief discussion on the comparative value of experiments on different laboratory animals.

The two remaining memoirs are by Prof. John Cardamatis, on sanitary measures and malaria epidemics of Athens, and by H. B. Day and Prof. A. R. Ferguson, on a form of splenomegaly, with hepatic cirrhosis, endemic in Egypt. Both memoirs are illustrated by photographs.

In the *Annals of Tropical Medicine and Parasitology*, vol. iv., part iv., are published two reports of the expedition of the Liverpool School of Tropical Medicine to Jamaica. The first of these reports is by Mr. Robert Newstead, on the ticks and other blood-sucking Arthropoda of Jamaica. The author gives most interesting bionomical notes, as well as systematic descriptions, of these pests, and suggests measures to be taken for the extermination of ticks. The most active enemies of ticks were found to be birds, especially the tinkling grackle (*Quiscalus crassirostris*), the parrot-billed blackbird (*Crotophaga ani*), and the domestic fowl. In the stomach of Crotophaga there were also found specimens of the "green stink-bug" (*Loxa flavicollis*), an observation of great bionomical interest, since this insect, though possessed of an odour which is "horribly offensive," has a protective green coloration. The second report is by Dr. W. T. Prout, on malaria. After discussing the nature and etiology of the disease and its occurrence in Jamaica, the author gives an account of anti-malarial measures and their effects in Jamaica and elsewhere, and suggests practical means for combating the disease.

PRODUCTION AND UTILISATION OF MOLASSES.

THE production of molasses is an important factor in the cane-sugar industry, and has received a good deal of attention in sugar-growing countries. Molasses constitute the thick mother liquor left after the sucrose has crystallised out, and, no matter what artifice be adopted, there is a point beyond which it seems impossible to obtain any more crystals, the sugar being held back by the foreign bodies present. Hertzfeld has shown that the formation of beet-sugar molasses is due to the mineral matter originally present in the juice, or added in the liming process, reacting with the sucrose to form non-crystallisable compounds. Prinsen Geerligs has proved that similar compounds are formed in working up cane sugar. The problem is complicated here by the presence of glucose, which reacts more readily with the mineral substances than does sucrose. In this way is explained the definitely established fact that, the larger the proportion of glucose to mineral matter, the greater the recovery of sugar is likely to be. There appears also to be a physical factor involved; gummy matter is always present, which apparently coats the small crystals and prevents their growth.

The whole subject is discussed very fully in an illuminating article in a recent issue of the *Agricultural News*, one of the publications of the West Indian Department of Agriculture. It is further pointed out that during the past season the muscovado molasses of Antigua and Barbadoes, and to a lesser extent of other West Indian islands, has obtained a remarkably high market price, higher, indeed, than the value of the sucrose present. The chief consumers seem to have been the fishermen and lumbermen on the North American continent. There has been a simultaneous rise in the market value of the exhausted vacuum-pan molasses of Antigua. The problem of storage, therefore, assumes considerable importance; it is complicated by certain bacterial changes which are very liable to set in. But these changes are not inevitable, and with greater care in the manufacture the "souring" which so greatly reduces the market value can be to a large extent avoided. The composition of the various grades of molasses is given as follows:—

	Muscovado molasses (Antigua) per cent.	Centrifugalled first molasses per cent.	Centrifugalled second molasses (exhausted) per cent.
Sucrose ...	50 to 55 ...	40 to 60 ...	20 to 40
Glucose ...	5 ,, 15 ...	7 ,, 20 ...	15 ,, 40
Non-sugar ...	3 ,, 8 ...	— ...	—
Ash	3 ,, 5 ...	3 ,, 6 ...	3 ,, 10
Water	24 ,, 30 ...	25 ,, 28 ...	17 ,, 28

The first molasses can be made to yield a further crop of cane sugar by re-boiling, but the second molasses cannot, and are therefore said to be exhausted.

The problem in Hawaii is very different in character. The molasses obtained there are not of the muscovado type, and consequently have no commercial value as human food. It is estimated that something like fifteen million gallons are obtained annually, of which about ten millions are used as food for stock. There is little doubt that this would be the most economical way of utilising the remainder, but, unfortunately, the number of stock kept on the islands is insufficient for the purpose. Of the other twenty million gallons some is burnt as fuel, some is put on the land as fertiliser, and some is run into the sea and wasted. Decided benefit has followed the use of molasses as fertiliser in Mauritius, and there is some reason to suppose that the sugar increased the amount of nitrogen fixation in the soil; in consequence, the manurial value is higher than one would expect from a consideration merely of the amount of nitrogen and mineral matter present. These favourable results, however, are not obtained in Hawaii, and experiments have been instituted at the Experiment Station of the Hawaiian Sugar-planters' Association to find out whether molasses could profitably be converted into alcohol. Something more than 50 per cent. of sugar is present, of which 83 per cent. can be converted by fermentation into alcohol. The effect of varying conditions has been investigated and the native yeasts described.

THE AUSTRALIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE Australian Association for the Advancement of Science held its inaugural meeting in Sydney in September, 1888, and met there again in 1898; in January, 1890, it visited Melbourne, and again in 1901; since then sessions have been twice held at Adelaide, Hobart, and Brisbane, and once at Christchurch and once at Dunedin, in New Zealand; its next meeting will be held in Sydney in 1911.

As a rule, the meetings have been held in the capitals of the Australian States at intervals of ten years; as the inland towns like Bathurst and Ballarat become larger and better able to provide the requisite meeting-rooms and other accommodation, they will also be visited.

One great disadvantage under which the association suffers is the very great distances which the members have to travel; the nearest meeting-places are between 500 and 600 miles apart, so that members living in Brisbane, Melbourne, and Hobart have to travel those distances to attend a meeting in Sydney, and members from South Australia and New Zealand have to travel about 1200 miles, and those from Western Australia nearly 2500 miles; when the meeting is in New Zealand all the Australian members have to undergo a sea voyage of about five days at least, and some a longer one, with perhaps some hundreds of miles of railway travelling in addition.

People in England do not generally realise these great distances; the above towns appear to be quite close on an ordinary map, especially as the maps of Australia are usually on a much smaller scale than those of Europe and America.

It is partly on account of these great distances that the meetings are no longer held annually, but in alternate years; the yearly expenditure of time and money was too great a tax upon the working members, for, to their credit, it is they who, in spite of these disadvantages, attend the most regularly. The association has, so far, not had funds placed at its disposal to reduce the travelling and other expenses of its members (the British Association has received considerable sums for this purpose when visiting Canada and South Africa); the members, however, are granted return railway tickets for a single fare by the Government railways, and certain of the steamship companies allow a reduction of 20 per cent. off their ordinary fares. The attendance of members and associates has varied from about 600 to nearly 1200.

The Australian Association was founded with the same aims and objects as the British Association, and its rules are very similar; the subscription is lower, viz. 1*l.* for members and 10*s.* for associates (ladies and students) for each session, and there is no longer an entrance fee. The sessions last about a week, and the work is distributed over various sections.

Lectures to working men and others form a popular feature; also garden-parties, conversaziones, and similar social gatherings, which greatly help to bring the members together and afford opportunities to make and renew acquaintances. Local excursions to places of interest and to engineering and other works are also much appreciated, as well as the longer botanical and geological excursions.

The association does a good deal of work by means of special committees for investigation and research; money grants are made to these where necessary from the interest of the research fund (now nearly 3000*l.*), which has been slowly built up from the savings from members' subscriptions, but this has only been rendered possible by the fact that the Australian and New Zealand Governments have liberally provided for the printing of the volume of reports and proceedings. All other expenses are paid for out of the subscriptions, and the excursions are made self-supporting; no funds are provided by the towns visited for the entertainment of the members, as is done for the British Association, but private hospitality is gladly offered to visiting members.

The principal working members are naturally the scientific members of the Australasian universities, societies, museums, Government departments, and other institutions, although, as is seen from the association's publications, many others contribute valuable papers.

There is no doubt that the peripatetic meetings of the association have done much to cause many of the residents in the districts in which it has met to take an interest in scientific matters and do much for its advancement; the effect is also noticeable in the increased output of the original work of the local universities and similar institutions.

One of the greatest benefits of the meetings of the association is that it enables workers to meet and discuss matters of mutual interest, and there is no doubt that this acts as a stimulus of immensely greater value than the reading of even hundreds of pages of printed reports.

The association has one medal to award, viz. that founded in memory of the late Baron von Mueller.

The association has published eleven volumes of reports; these are of about the same size as the annual volumes of the British Association; they are well illustrated by maps, plans, and numerous reproductions of photographs. These volumes are distributed gratuitously to about 300 scientific societies and institutions throughout the world, so that they are fairly accessible to anyone interested in Australasian science, even in places so widely separated as Bucharest, Monte Video, Seoul, Port Louis, and Pietermaritzburg.

As an example of the contents of the volumes, the last report published, viz. that of the Adelaide meeting for 1907 (the report of this year's meeting, held at Brisbane, is now being printed), may be referred to; after the list of officers, sections, committees, and other preliminary matters (thirty-two pages) there is the interesting address by the president, the late Dr. A. W. Howitt, C.M.G., upon personal reminiscences of Central Australia and the Burke and Wills' expedition, which affords a good deal of hitherto unpublished information upon this disastrous expedition; this is followed by the addresses of the presidents of the sections, beginning with Section A, for mathematics, astronomy, and physics, by E. F. J. Love, on the theory of the Voltaic cell; Section B, chemistry and metallurgy, by R. C. Stiehl, on progress in rapid oxidation processes applied to copper smelting, a most important subject in Australia; Section C, geology, by A. Gibb Maitland, Government geologist of Western Australia, on recent advances in the knowledge of the geology of Western Australia; Section D, biology, a century of botanical endeavour in South Australia, by J. H. Maiden, Government botanist of New South Wales; Section E, geography, by Thomas Walker Fowler, upon Australasian geography; Section F, anthropology and philology, by R. Parkinson, of Ralum, Bismarck Archipelago, on totemism and its possible origin; Section G, I., social and statistical science; Section G, II., agriculture, by F. Anderson, professor of mental philosophy, Sydney University, on Liberalism and Socialism, and the outlook of agriculture in Australia, by T. Cherry, Director of Agriculture, Victoria; Section H, engineering and architecture, no address; Section I, sanitary science and hygiene, by Dr. R. Greig-Smith, on air infection; Section J, mental science and education, by Dr. Henry Laurie, professor of mental philosophy, Melbourne University, on materialism and evolution.

Next, on p. 263, follow the reports of committees:—

(1) For the investigation of glacial phenomena in Australasia. This contains the most recent results of the investigations into the Cambrian (?) and Permo-Carboniferous glacial history of South Australia, Victoria, Tasmania, West Australia, and New Zealand, and is supplementary to reports by this committee published in several of the association's previous volumes. (2) For the biological and hydrographical study of the New Zealand coast. (3) On New Zealand food fishes. (4) On terrestrial magnetism in Australia and New Zealand. (5) On seismological phenomena in Australasia. This committee has worked continuously for several years, and has issued several valuable reports. (6) On a uniform system for the nomenclature of igneous rocks in Australasia.

Previous volumes contain other valuable reports from committees upon other subjects; amongst them the following may be mentioned, as they give a general idea of the matters which have engaged, and are still engaging, the attention of the association:—

(1) Upon a uniform system of spelling native names. (2) To inquire into and report upon the teaching of science in primary and secondary schools, technical colleges, and universities. (3) To investigate and report upon the best method of utilising diamond-drill bores for the determination of underground temperatures. Deep bores are being put down in many parts of Australia by the Governments and by private individuals for ordinary water supplies and for irrigation. (4) For collecting and cataloguing geological photographs and surveys. (5) For cataloguing marine Mollusca. (6) For cataloguing the minerals of Australia. (7) To investigate the tides of South Australia. (8) The movements of New Zealand glaciers. (9) The fertilisation of the fig in Australia. (10) On rust in wheat. (11) On Antarctic exploration. (12) On the protection of native birds and animals. (13) On improvements in museums as a means of popular education. (14) On the Adulteration of Food Acts of the Australian Governments. (15) On the chemical compositions and properties of the mineral waters of New Zealand. (16) On the vernacular names of Australian birds.

Next follow the papers read before the sections; several of these, in common with papers in previous volumes, are of a high order, and will be of permanent value. It would be rather difficult to make a selection of these papers, and much space would be occupied by even their titles, but it may perhaps be mentioned that in astronomy, mathematics, and physics there are eleven papers; in chemistry, &c., ten; geology, twenty; biology, eleven;

geography, seven; anthropology and philology, four; social science and statistics, six; agriculture, eight; engineering and architecture, seven; sanitary science and hygiene, nine; and in mental science and education, four; this section is a very popular one with teachers and others interested in education, and the attendance is usually very large.

The association has made several recommendations to the various Australasian Governments and other authorities, and in the majority of cases these have been sympathetically received, and in certain cases carried out. One of the first recommendations was to the British Admiralty, suggesting that the ocean between Australia, New Zealand, and Tasmania should be named the Tasman Sea; this was agreed to, and the name was at once ordered by the Admiralty to be printed on all charts; previous to this there was some difficulty in speaking of this hitherto nameless part of the Pacific.

The association has also made requests for the reservation of certain areas in Australia and New Zealand for the preservation of the native flora and fauna, some of these have been agreed to; a notable one is the reservation of the island upon which the Tuatara lizard is found. Another smaller reservation was that of a sandstone quarry at Bondi, near Sydney, showing a remarkable columnar or prismatic structure.

Amongst other recommendations made at various meetings to the Australian and New Zealand Governments are the following, some of which have been given effect to:—

(1) That the Federal Government should endeavour to obtain data in the Indian Ocean for long-distance weather forecasting.

(2) The installation at Perth, Western Australia, of a complete set of magnetographs for the continuous registration of magnetic variations; also installations at Brisbane, Port Darwin, and Hobart similar to those at Sydney, Melbourne, &c. One has recently been installed at Adelaide in response to the association's suggestions.

(3) That the Australian and New Zealand Governments should adopt additional measures to prevent the further extension of tuberculosis amongst cattle and swine.

(4) Recommending the teaching of hygiene and the medical inspection of school children.

(5) That the New Zealand Government should undertake the magnetic survey of the Macquarie Islands now that the survey of the main islands has been completed.

(6) The Australian Governments were urged to take more effective steps for the conservation of forest areas.

The Federal Government was requested in 1902, before determining upon the site of the Federal capital, to appoint a board, consisting of architects, engineers, surveyors, medical and business men, to inquire and report upon the sites proposed; also to reserve a site for a national museum and for the housing of scientific societies and institutions in the proposed Federal capital. In 1898 successful recommendations were made to the New South Wales Government to proceed with the boring at Funafuti.

So that members may come prepared for the discussions, it has been agreed to arrange for the preparation of papers on subjects of which notice had been given at a previous meeting. Arrangements are being made for the preparation and publication of bibliographies which would be beyond the powers of an unaided individual.

Some of the papers of permanent value might usefully be reproduced in English publications, for in spite of the volumes of reports being widely distributed, a paper published at the Antipodes finds very few readers elsewhere, because on receipt of the volumes by an institution they are usually put on the library shelves, and there they remain.

The desirability of inviting the British Association to visit Australia has been considered and warmly advocated at different times since 1885; a reference to the proposed invitation will be found on p. xxiii of the present volume, in which it was suggested at the Adelaide meeting in 1907 that a sum of 10,000*l*. to 20,000*l*. should be provided to defray part of the travelling expenses of the visitors, and that the invitation should be issued for not earlier than 1913, so as to leave plenty of time to make proper arrangements.

The permanent offices of the Australian Association are in the house of the Royal Society of New South Wales, which has recently provided accommodation for other scientific societies, so as in a small way to afford some of the advantages which Burlington House provides for certain of the English societies; the Sydney societies thus housed have already found much mutual advantage from being under one roof.

A. LIVERSIDGE.

EPIDEMIC DISEASE AMONG THE NORTH AMERICAN INDIANS.

IN the Bulletin of the Johns Hopkins Hospital for November Dr. H. U. Williams discusses the origin of epidemic diseases among the North American Indians.

He believes that these American races developed an extremely small number of infectious maladies. Many of the most deadly kind—small-pox, leprosy, bubonic plague, glanders, anthrax, rabies—were the result of the introduction of infection from Europe. With regard to tuberculosis, diphtheria, influenza, gonorrhœa, beri beri, and malaria, the case is more doubtful; but these maladies do not seem to have been noticed among the native tribes by the earlier explorers. The origin of syphilis and yellow fever alone can with some degree of certainty be assigned to American soil. As contributory causes to this immunity from infection, the dispersion of the tribes in isolated camps, and the lack of domestic animals (the horse being connected with glanders, the cow with tuberculosis, and the goat with Malta fever), may have prevented the spread of disease.

Dr. Williams further attempts to identify the serious epidemic which prevailed on the western coast about 1612–20. When the Puritans appeared on the scene they found this region almost entirely depopulated, and they regarded the epidemic as a dispensation of Providence which had removed the savages to make room for the Europeans. It seems probable that this terrible malady was introduced by foreign settlers. It is very generally supposed to have been an outbreak of small-pox or yellow fever; if this be the case, it is remarkable that the early travellers should not have described it under those names. It is significant that in 1614 that ruffian, Hunt, kidnapped several natives, who were carried to Europe, and after a time those who survived were brought back to their native country. Bubonic plague prevailed in London from 1603 to 1611, and sporadic cases were reported in the following years. The European settlers in America seem to have escaped the disease; and if, as seems most probable, the terrible mortality among the Indians was due to plague, the settlers may have been protected, as in the recent epidemic in India, by the fact that they were cleanlier in their habits and better shod than the native population, and that they were thus less liable to contagion through wounds or insect bites.

OPTICAL ACTIVITY WITH NO ASYMMETRIC ATOM.

AN important paper by Profs. Perkin, Pope and Wallach on optically active substances containing no asymmetric atom appears in the Chemical Society's Journal for November. The substance described is 1-methyl*cyclo*hexylidene-4-acetic acid, and its structure is represented by the formula

$$\begin{matrix}CH_3 & & CH_2.CH_2 & & & & H\\ & \overset{(1)}{C} & & & \overset{(4)}{C}=\overset{(7)}{C} & & \\ H & & CH_2.CH_2 & & & & CO_2H\end{matrix}.$$

The carbon atom (1) is linked to two identical chains of atoms, and is therefore not asymmetric. The optical activity of the compound depends on the fact that the plane of the $\genfrac{}{}{0pt}{}{CH_3}{H}\!>\!C=$ group is at right angles to the plane of the $=C\!<\!\genfrac{}{}{0pt}{}{H}{CO_2H}$ group, the former being perpendicular to the plane of the hexagonal ring and the latter identical with it; the dissimilarity of the —H and —CH_3 radicles destroys the symmetry on either side of the plane of the ring, whilst the dissimilarity of the —H and —CO_2H groups destroys the symmetry about the perpendicular plane. The compound therefore fulfils the fundamental condition for enantiomorphism, namely, that no plane of symmetry shall exist. By way of contrast it may be noted that the compound

$$\begin{matrix}CH_3 & & CH_2{\cdot}CH_2 & & H\\ & C & & C & \\ H & & CH_2{\cdot}CH_2 & & CO_2H\end{matrix}$$

could not exist in enantiomorphous forms or exhibit optical activity, because the four radicles are all situated in a plane (perpendicular to that of the ring) which would thus form a plane of symmetry of the molecule.

Extraordinary difficulties were encountered in effecting the resolution of the acid. Owing to its weak basicity the salts were very ill-defined, and the brucine salt by means of which the resolution was finally accomplished separated from its solutions as an oil which only slowly became crystalline. Again, the brucine salts of the enantiomorphous acids were so similar that an exceedingly tedious process of re-crystallisation was required before they could be obtained with a constant rotatory power, and even then the acids separated from them were not homogeneous, but proved to be capable of further resolution. Evidently the salts are not only similar, but partially isomorphous. Finally, however, both acids were obtained in a pure state, the *l*-acid giving $[\alpha]_D-81{\cdot}1^\circ$ and the *d*-acid $[\alpha]_D+81{\cdot}4^\circ$ in absolute alcohol (0·145 gr. in 20 c.c.).

TECHNICAL EDUCATION IN MANCHESTER.

THE sixth annual report of the Manchester Education Committee, dealing with the work of the year 1907–8, has now been published, and provides an excellent example of the way in which an educational authority can build up a complete and duly correlated system of education to meet the precise needs of the area under its charge. The report deals fully with higher, secondary, and elementary education.

The section dealing with higher education is concerned with the year ending in October, 1908, and deals chiefly with technical education. The number of individual day and evening students enrolled at the Municipal School of Technology for the session ending July 31 was 5299, as compared with 5149 for the previous session. The number of individual students enrolled in the day departments was 661, as compared with 651 for the session 1906–7. The class entries for the session were 11,379, against 10,979 for the session 1906–7. These figures do not, however, include the class entries in respect of students in the day departments of the school. Computing the total volume of work of the evening departments in student-hours—that is, by multiplying the number of students enrolled by the total number of hours' instruction given during the session—it was found to be 459,805. The actual volume of work, namely, the total number of hours of instruction multiplied by the actual attendances, was 302,162 student-hours, or 60 per cent. of the total volume of work. Whichever method of computation is adopted, the result obtained shows a marked increase on the previous session.

The imperial grant received year by year increases steadily, amounting during 1906–7 to 9773*l*. The capitation grant paid by the Lancashire County Council in respect of students outside the Manchester area was, for 1907–8, 1226*l*. The Cheshire County Council compounds, so far as its students are concerned, and from this source the school received 400*l*.

It is interesting to notice that a certificate has been instituted this year for students attending the engineering apprentices' course, held on Mondays from 9 a.m. to 6 p.m. throughout the session. To satisfy the conditions of award, students must pass all the prescribed examinations upon completion of the two years' course of study. The certificate has now been awarded to thirty-seven students, who have attended the course during the past four sessions. A similar day course for apprentice painters and decorators has also been inaugurated. The committee of the school has had under consideration the question of extending the facilities to apprentices in other industries for instruction and training during one whole day a week, so as to relieve them from attendance at the evening classes, and at the same time to give additional time and opportunity for homework and study in the evening. After consultation with the Master Plumbers' Association of the Manchester and Salford district, a scheme has been drawn up for apprentice plumbers on the same lines as the course for apprentice engineers.

During the past year opportunity has been taken to improve and develop the organised courses of instruction in several of the evening departments in order more thoroughly to systematise the training given, and to bring the various subjects of the respective evening courses into closer organic relation. The courses in the departments of mechanical engineering, electrical engineering, architecture and builders' work, municipal and sanitary engineering, and textile manufacture, are thus graduated and organised to cover a period of three or five years, leading up to the evening certificate or diploma of the school, as the case may be.

A large number of tests has been carried out during the year for various firms in Manchester and district, and the facilities which the school offers for mechanical and electrical tests, and tests and analyses of a chemical nature, are taken advantage of increasingly, as shown by the fees received, which have increased from 119*l*. in 1904–5 to 319*l*. in 1906–7, and 352*l*. in 1907–8. The members of the staff have been responsible during the session for a considerable amount of original research, a large portion of which has been embodied in papers read before various scientific societies, and published in the journals of the scientific and technical Press.

Not only does the committee govern the Municipal School of Technology, but aids higher education in other ways. It recommended to the City Council the grant of 4000*l*. received by the Victoria University of Manchester, and is responsible for the grants received from the council by the secondary schools of the district.

ON THE INVENTION OF THE SLIDE RULE.[1]

SOME modern writers attribute the invention of the rectilinear slide rule to Edmund Gunter, others to William Oughtred, but most of them to Edmund Wingate. This disagreement is due mainly to lack of opportunity to consult original sources. It is the purpose of this paper to demonstrate that Wingate never wrote on the slide rule, and that Oughtred is the inventor of the rectilinear as well as the circular type.

It was pointed out by Prof. De Morgan that Gunter invented Gunter's line or scale, but that he did not invent the slide rule. As Gunter's works are found in most large libraries, the correctness of this statement can be readily verified. This scale was not a slide rule, for it had no sliding parts.

No one denies that William Forster published in London in 1632 a book entitled "The Circles of Proportion," which described the circular slide rule invented by William Oughtred. In the dedication it is said that Oughtred invented also the straight-edge type; but this was not described until 1633, when Forster brought out an "Addition unto the Use of the Instrument," with an appendix entitled "The Declaration of the Two Rulers for Calculation," which described the rectilinear slide rule.[2]

The question remains, Did Wingate invent the straight-edge slide rule, and is he entitled to priority over Oughtred? De Morgan maintained that Wingate never wrote on the slide rule,[3] but he had not seen all of Wingate's books. Thus he admits[4] that he had not examined Wingate's "Of Naturall and Artificiall Arithmetique," 1630, yet this very book is quoted by several recent writers as describing the slide rule[5]; but these and all writers who name Wingate as the inventor invariably fail to give evidence which would show that they had actually seen the book to which they refer. We have gathered information about all Wingate's mathematical books which De Morgan did not examine. We shall state where copies can be found, so that the data given here can be verified by those who are near the libraries named. We take up Wingate's books, one after the other, and show that none contains the slide rule.

---

[1] Abstract of a paper, by Prof. F. Cajori, read before the Section of Mathematical and Physical Science of the British Association, Winnipeg, August 27.

[2] For extracts see Cajori, "History of the Logarithmic Slide Rule." (New York: *Engineering News* Publishing Co., 1909.)

[3] "Penny Cyclop.," Art. "Slide Rule," and Wingate, Edmund, "Arithm. Books." Pp. 38, 42. (London, 1847.)

[4] "Arithm. Books,' p. 48.

[5] A. Favaro in "Veneto Istituto Atti" (5), 5, 1878–9, p. 500; Mehmke in "Encyklop. d. Math. Wiss.," vol. i., p. 1054. (Leipzig, 1898–1904.)

(1) "L'Usage de la Règle de Proportion," Paris, 1624. De Morgan's assertion that this book describes nothing more than Gunter's scale[1] is corroborated by P. M. N. Benoit,[2] who examined copies in the Bibliothèque nationale and the Bibliothèque Mazarine in Paris. There is a copy in the Bodleian Library.

Wingate brought out in 1626 in London a translation under the title "Use of the Rule of Proportion." Later editions appeared in 1628, 1645, 1658, and 1683. De Morgan saw the 1645 edition, a copy of which is in the British Museum. Wingate died in 1656.

(2) "Arithmétique logarithmique," Paris, 1626. De Morgan described this book.[3] He saw also the "Logarithmeticall Table," London, 1635, which is anonymous, but is attributed to Wingate.[4]

(3) "Construction and Use of the Line of Proportion," London, 1628. Copy in the British Museum. The "line of proportion" here described is merely a mechanical table of logarithms. There are no sliding parts.

(4) "Of Naturall and Artificiall Arithmetique," London, 1630. Copy in the Bodleian Library. Describes only the instrument named in the preceding text. The first part of this book was enlarged by John Kersey the elder in 1650 under the new title "Arithmetique Made Easie." De Morgan saw the editions of 1673 and 1760.[5] The second part was re-edited by Wingate in 1652. Copy in the British Museum. The instrument described here is still the "line of proportion."

(5) "Ludus Mathematicus," London, 1654, 1681. De Morgan[6] inspected the first edition.

(6) "Use of the Gauge-rod," London, 1658 (second edition).

(7) "The Clarks Tutor for Arithmetick and Writing . . . being the Remains of Edmund Wingate," London, 1671. Copies of both books in the Bodleian Library. Neither contains an account of the slide rule.

MASONRY ARCHES.

A MEMOIR dealing with a subject of great interest to the engineer has recently been issued as a Drapers' Company Research Memoir.[1] It must be admitted that the ordinary treatment of the masonry arch is by no means satisfactory, and therefore any solution of the problem which would give more accurate and trustworthy results without involving excessive labour in the necessary calculations would be welcomed by every engineer who may in the course of his professional duties have to deal with the design and erection of masonry or brick arches.

After discussing the ideal arches for different load conditions, the authors show that for the fairly flat arches of modern practice designed to carry (1) a uniform load per foot run of the rib, or (2) a vertical load rising to a horizontal at a height $l^2/8r+r/6$ above the central line at the crown, the elliptic arch is the proper design.

The rest of the memoir is devoted to an investigation of the extent of the applicability of the elliptic arch. It is shown that for the loads usual in masonry arches the elliptic arch is only closely approximate to the ideal if the ratio of rise to span be small, this latter condition involving large horizontal thrusts and great compressive stresses.

The authors then show that a close approximation to the arch the line of pressure of which coincides with its central line can be obtained with no great labour of calculation, and such an arch they term a pseudo-elliptic arch. The necessary equations to give the required solution are obtained, and an example is worked out in detail to show the application of the method and to prove that the labour of the necessary calculation is not a serious obstacle to the employment of this method. The memoir is illustrated by six plates reproduced from actual drawings.

The applied mathematics department of University College is to be congratulated on this valuable addition to the series of research memoirs dealing with difficult engineering problems for which Prof. Karl Pearson and his students have been responsible. T. H. B.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GRADUATES of the late Royal University of Ireland who desire to be registered as graduates of the Queen's University of Belfast, or enrolled as members of Convocation, should communicate as early as possible with the secretary of the latter University. The first meeting of Convocation must be held within the next four months.

WE learn from *Science* that, according to figures available in the office of the auditor, the University of Chicago holds investments representing permanent endowment that amount to 2,974,000*l*. In addition, its buildings and grounds devoted entirely to university use represent 1,783,540*l*.; equipment, scientific apparatus, furniture, &c., being put at 383,260*l*. additional. These figures do not include the funds destined for the erection of the Harper Memorial Library, estimated in round figures to cost 180,000*l*., nor the cost of the classical building, the construction of which is in contemplation, and on which about 50,000*l*. will be expended.

DR. CHARLES GRAHAM, at one time professor of chemistry at University College, London, and a prominent member of the Society of Chemical Industry, who died on November 13, has left the residue of his estate for medical research. The amount available will probably be 35,000*l*., and it is left to the Senate of the University of London to found a fund, to be known as the Charles Graham Medical Research Fund. The fund is to be applied in aid of any research carried on by a teacher or student of the school of advanced medical studies of the University College Hospital for the prevention, cure, or alleviation of human disease or suffering. If any student or teacher conducts a research which is considered of sufficient merit a gold medal of appropriate value is to be awarded to him. The committee of the school is also to pay to such teacher or student conducting the research an annual sum not exceeding 200*l*. per annum for two years, such person to be known as the "Charles Graham Student in Pathology."

THE Department of Agriculture and Technical Instruction for Ireland has issued a syllabus (Circular 70) of the examination which it proposes to hold in the principles, methods, and history of education, with special reference to science teaching. The examination will be held in June of each year. The examination is provided for candidates seeking recognition of qualification to teach science. Among the subjects included in the syllabus are:—The general characteristics of the curriculum and methods of instruction in science as determined by the laws of general development; the correlation of science with other subjects of the curriculum. The methodology of instruction in science as determined by the laws of development of knowledge; the functions and relations of laboratory work and class-teaching. The critical study of the history of a special branch of science so far as it bears upon the teaching of the subject. The use of note-books and textbooks in science teaching; methods of recording and treating observational data. The construction and use of pictorial illustrations, diagrams, and models; the construction of apparatus. Laboratory organisation and management.

THE "Regulations for Secondary Schools" of the Board of Education lays it down that in all fee-charging secondary schools free places must be offered, under certain conditions, at the beginning of each school year to pupils entering from public elementary schools. The number of such places offered must ordinarily be 25 per cent. of the total number of pupils admitted to the school during the previous year, or, in the case of a new school, at its opening, but this percentage may be reduced or varied by the Board on sufficient grounds in the case of any particular school. A return has just been issued showing the number and names of the fee-charging secondary schools receiving the Board's full grant in which the 25 per cent. of free places has been reduced or varied on grounds deemed sufficient by the Board of Education. The return shows there are 865 secondary schools receiving from the Board the full scale of grant of 5*l.* for each registered pupil between twelve and eighteen years of age. At two of these schools no fees are charged, 746 are required to offer 25 per cent. of free places, and in the remaining 117 a lower percentage is required. The grounds for variation or reduction of the normal percentage of free places fall roughly under three heads, viz. financial circumstances, the fact that there is an adequate provision of free places in neighbouring schools, and the existence of a large percentage of boarders in the school. In fifty-three cases the number of free places has been reduced from 25 per cent. to 10 per cent., in twenty-nine cases to 12·5 per cent., in thirteen cases to 15 per cent., and in all other cases where a reduction has been allowed to 20 per cent.

THE eighth annual report, which deals with the work of the year 1908–9, of the executive committee of the Carnegie Trust for the Universities of Scotland has now been issued. The committee states that reports of the independent authorities who have examined the records of the year's work under the research scheme of the trust give evidence that its past success is being well maintained. The committee acknowledges the assistance rendered by the universities in providing the scheme with so many able workers and in affording accommodation and supervision in their various laboratories. We notice that applications for fellowships, scholarships, and grants for 1910–11 must be lodged on or before April 1 next with the secretary of the trust, from whom application forms and regulations can be obtained. The expenditure for 1908–9 upon the scheme of fellowships, scholarships, and grants, and upon the laboratory, was respectively 6861*l.* and 1992*l.*, towards the latter of which the Royal College of Physicians and the Royal College of Surgeons together contributed 1025*l.* The second quinquennial scheme of distribution, which opened with the year under review, besides making contributions of 65,250*l.* to buildings and permanent equipment, and 20,500*l.* to libraries, will at the close of the period of five years have increased the resources of teaching in the four university centres by permanent endowments amounting to 87,500*l.*, while it will at the same time have afforded during the five years an annual income of some 4150*l.* to meet ordinary expenditure. Statistics of the payment of class fees for 1908–9 give the total number of beneficiaries as 3553, the total amount of fees paid as 47,071*l.*, and the average amount of fees paid per beneficiary as 13*l.* 4*s.* 11*d.*, an increase as compared with the preceding academic year of 284 beneficiaries, of 3815*l.* in the total expenditure, and of threepence in the average amount per beneficiary. During the year 257*l.* 10*s.* 6*d.* was refunded voluntarily on behalf of eleven beneficiaries for whom class fees had been paid by the trust.

THE recommendations, made jointly by several of its subcommittees, to the London Education Committee for the organisation of a system of central schools in London have been adopted by the Education Committee, with the exception of a few relating to certain points concerning the teaching staff, and the consideration of these has been deferred. A system of schools is to be established giving an educational course not provided in existing elementary or secondary schools, and the new schools, which will be known as central schools, will have either an industrial or a commercial bias, or both. These schools will take the place of the existing higher elementary and higher grade schools, and will be fed by contributions from surrounding schools, as most of the higher grade schools are at present. The curriculum will provide in all cases for manual and practical work, and, in the case of girls, for instruction in domestic subjects. The curriculum of each school will be considered specially, and be determined with the view of meeting the needs of the district. Pupils will be selected between the ages of eleven and twelve, and parents will be given the opportunity of choosing either a secondary school or a central school for these children. The schools will be organised on a four years' course, and provision will be made for bursaries to be held by pupils on their attaining the age of fourteen. These bursaries will not exceed 500 in number, and will consist of maintenance grants from the age of fourteen at the rate of 10*l.* a year. The total annual cost of this arrangement is estimated at 7500*l.* It is intended that the number of central schools shall be fewer than the present higher elementary and higher grade schools, and shall be carried on under the ordinary regulations of the Board of Education, and in this way be free from the restrictions imposed by the higher elementary schools' regulations. In order that the parents of candidates for admission may be given an opportunity of realising the advantages afforded by the new schools, it is intended to issue a short descriptive pamphlet, and the parents are to be encouraged to seek personal interviews with the school managers and head teachers.

THE eighth annual meeting of the North of England Education Conference will be held at Leeds, in the University buildings, on January 6–8, under the presidency of Sir Nathan Bodington, Vice-Chancellor of the University. The general conference on Friday morning will be devoted to a discussion on the relation of elementary schools to technical schools (day and evening), which will be introduced by papers by Prof. M. E. Sadler, of Manchester, and Mr. James Baker. Mr. J. H. Reynolds and Mr. A. C. Coffin will open the discussion. The subject for the general conference on Saturday morning will be education abroad and in England—a comparison, introduced by papers by Mr. J. C. Medd and Mr. Otto Siepmann, head of the modern languages department, Clifton College. Mr. Cloudesley Brereton and Dr. R. M. Walmsley will open the discussion. The sectional meetings on Friday afternoon will be devoted to the following four topics:—(1) independent study and self-help in schools; (2) co-operation between employers and education authorities; (3) colour-study in relation to general art and to trade, and modern developments of applied art instruction; and (4) the teaching of geography and history in relation to one another. The sectional meetings on Saturday afternoon will be devoted to the four subjects:—(1) physical training in schools, with special reference to the new scheme of the Board of Education; (2) do we teach too many subjects in the primary schools? (3) modern ideas on general art instruction; and (4) the relation of the State to the training of teachers of domestic science, and their relation to the university. The last subject will be introduced by Prof. Smithells, F.R.S., and Miss M. Atkinson. It will be seen that the organising committee has selected a series of topics of wide interest and importance. The principal speakers are experts in their subjects. As a good attendance is already guaranteed, the conference should be one of particular interest and utility. The social side of the conference will be promoted by a conversazione at the University on Thursday evening, January 6, and by a reception by the Lord Mayor in the City Art Gallery on Friday evening, January 7. The usual publishers' exhibition will be liberally accommodated in the large physics laboratory at the University, and the comfort of delegates has been carefully considered in the provision of writing, smoking, and conversation rooms. The technological departments of the University will be open to delegates throughout the conference.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, December 14.—Mr. G. A. Boulenger, F.R.S., vice-president, in the chair.—Dr. F. D. **Welch**: (1) Change of colour in a specimen of *Mellivora ratel* living in the society's gardens; (2) a comparative examination of three living specimens of *Felis tigris sondaica*, with notes on an old Javan male.—Dr. W. E. **Agar**: The nesting habits of the tree-frog, *Phyllomedusa sauvagii*. This frog makes a nest suspended from bushes overhanging a pool, into which the tadpoles drop when they are hatched. The nest is constructed from a number of leaves, the lower ends of which are drawn together and held so by a deposit of empty gelatinous egg-capsules, forming together a thick jelly. After oviposition the nest is closed with a similar mass of empty capsules, so that in a well-made nest not a single egg is exposed to the light and air.—Miss Ruth M. **Harrison** and Miss Margaret **Poole**: Madreporaria collected by Jas. J. Simpson and R. N. Rudmose-Brown from the Mergui Archipelago, Lower Burma, and from the Kerimba Archipelago, Portuguese East Africa.—F. E. **Beddard**: (1) Some notes upon *Boa occidentalis* and *Boa* (*Pelophilus*) *madagascariensis*; (2) notes upon the anatomy of monkeys of the genus Pithecia.—G. A. **Boulenger**: The ophidian genus Grayia. A contribution to the revision of the genus made necessary by an increased knowledge of African snakes.

Linnean Society, December 16.—Prof. E. B. Poulton, F.R.S., vice-president, in the chair.—Rev. T. R. R. **Stebbing**: (1) Report on the Crustacea Isopoda and Tanaidacea collected by Mr. Crossland in the Sudanese Red Sea; (2) Isopoda from the Indian Ocean and British East Africa. Among the Red Sea species, the most interesting novelty is one named *Lanocira latifrons*, in allusion to the peculiar widening of the frontal process. In British East Africa, Wasin has yielded a new genus and species meriting the significant appellation *Kalliapseudes makrothrix*, which may be rendered in the vulgar tongue as the "long-haired beauty of the Apseudidæ." The species is remarkable for the extensive fringes of feathered setæ on the mandibles, maxillipeds, and first gnathopods, as well as for the short, round-ended finger of its second gnathopods. In the Stanley Gardiner collection the new species *Apanthura xenocheir* is unique within its own family in the structure of the hand and finger of the first gnathopods. The new genus and species *Pontógelos aselgókeros*, of the family Eurydicidæ, from Mauritius, displays a prolongation of the first antennæ hitherto unexampled in that family. Several new species and a new genus of Epicaridea, isopods parasitic on other crustaceans, are described from specimens transmitted by Miss M. J. Rathbun, who had extracted them with great care from the crabs of the Stanley Gardiner Expedition. In one instance it proved that the maternal pouch of the parasite was occupied, not by the usual enormous mass of eggs, but by another parasite, probably itself an epicaridean, though strangely metamorphosed.—Prof. G. H. **Carpenter**: Pycnogonida from the Red Sea and Indian Ocean, collected by Mr. Cyril Crossland.—R. **Shelford**: A collection of Blattidæ preserved in amber, from Prussia.—A. W. **Waters**: The Bryozoa from collections made by Mr. C. Crossland, part ii., Cyclostomata, Ctenostomata, and Endoprocta. The collections dealt with only contain sixteen species, and these are nearly all known from the Mediterranean, while nine are British. In this and the previous paper ninety-nine Red Sea species and varieties are referred to; of these, thirty-four are known from the Atlantic, twenty-six from British seas, thirty-nine from the Mediterranean, thirty-four from Indian and neighbouring seas, seventeen from Crossland's Zanzibar collection, eight from Japan, thirty-five from Australia. The classification of the Ctenostomata is examined, and it is considered that the group Stolonifera of Ehlers must be divided into Vesicularina and Stolonifera. In the first there is usually a moderately thick, erect stem from which the zoœcia arise directly, and they all have gizzards, an organ not general in the Ctenostomata and probably confined to this group. In the Stolonifera as now reduced there is a delicate creeping rhizome expanding at intervals, and from these places the zoœcia arise, usually in pairs. There is no gizzard. The gizzards of the Vesicularina usually have a large number of sharp and irregular teeth surrounded by a band of strong muscles, but in Cryptopolyzoon the gizzard has but two teeth with nearly flat edges, called grindstone teeth.

DUBLIN.

Royal Irish Academy, December 13.—Dr. F. A. Tarleton, president, in the chair.—Prof. G. A. J. **Cole**: The "Picture Rock" or "Scribed Rock" near Rathmullan, in the county of Donegal. Attention has been directed to this rock on account of the supposed resemblance of the markings on its surface to casts of the footprints of animals. It proves to be a weathered face of spheroidal diabase (epidiorite), in which prisms of hornblende have developed from the two primary series of joints, and have spread inwards into the rock on either side. The portions of the rock which are thus strengthened to resist denudation stand up like the walls of boxes round about the residual cores of the spheroids, with a deeply weathered interval between them and the spheroids.—Prof. A. W. **Conway**: The motion of an electrified sphere. The problem of the distribution of electricity on a moving spherical conductor was treated, the velocity varying in any manner and the sphere having rotation. Two types of functions, called harmonicoid functions, were introduced, and by their aid a method of approximation to any degree of accuracy was obtained. The stability of the charge was found to be decreased. In quasi-stationary motion with a uniform field of force the distribution remains uniform if there is no Newtonian mass, but, if there is, a "cosine" distribution is produced, the extent depending on the Newtonian mass. In *all cases* the total masses transverse and longitudinal are the same as if the charge were uniform and rigidly attached to the sphere. A conducting electron will have the same dynamical properties as an Abraham electron of the same size and charge.

THURSDAY, JANUARY 6, 1910.

THE ETHER OF SPACE.

The Ether of Space. By Sir Oliver Lodge, F.R.S. Pp. xvi+156. (London: Harper and Bros., 1909.) Price 2*s.* 6*d.* net.

THIS book is a contribution to what the publishers describe as a "Library of Living Thought." In appealing to Sir Oliver Lodge for a book on the ether they could count on getting something which could certainly be called "thought," in the most exalted sense of the word, and would as certainly be alive. But, notwithstanding the many picturesque images with which the theme is illustrated, we must confess that we have found the book as a whole somewhat unsatisfactory. This is perhaps due to a certain indefiniteness of aim; some sections would seem to be addressed to the cultivated *dilettante,* and dwell at great length on very elementary matters, whilst others can hardly be appreciated except by the expert who is already conversant with the more abstruse parts of electrical and optical theory. Thus the primary notions of aberration are expounded very fully, whilst the theories of Michelson's experiments and of Fresnel's law of wave-velocity in a moving substance are treated with tantalising brevity. Again, the mechanical and optical details of the author's own experiments with the "ether machine" are given with a minuteness which in a work on the present scale rather tends to distract attention from the main point.

The ether has in its not very lengthy history undergone many transformations. The unsatisfactory elastic-solid medium of the last century, with its abundant provision for the explanation of non-existent phenomena, has at length gone, to the general relief. But the newer ether which is gradually being evolved in its place, with its ability to exercise force, and, at the same time, its utter indifference to forces exerted on itself, appears somewhat shadowy and mysterious. When the conceptions are resolved into their elements we are left with little more than what the mathematicians call a "vector-field." It might seem, indeed, that the physicist had only to take one step more, and hand over the whole medium, as a pure abstraction, to the mathematician, who, for his part, is disposed to welcome the gift with enthusiasm as affording, after a few improvements, an unexpected outlet for the theory of groups. His one regret is that he did not (as he confesses he ought to have done) invent the whole thing for himself.

Sir Oliver Lodge, like Lorentz, comes to the brink, but he will not take the plunge. The most interesting parts of this book are those in which he explains the lengths to which he is prepared to go in the effort to retain a mechanical basis for phenomena. He admits, indeed, that ordinary matter is an imposture, but he clings resolutely to something very real and very substantial in the background. He reproduces his recent arguments to show that if the inertia of the atoms of ordinary matter is merely the manifestation of that of a surrounding medium, the density which it is necessary to attribute to the latter is something like 10^{12} that of water. This seems at first sight like a nightmare, but it is in no sense incredible. Waiving details which can have no great influence on the result, it is, indeed, from the author's point of view, mathematically incontestable. He goes on to speculate on the origin of the forces which this medium can exert. Assuming a kinetic theory of force as the only one ultimately acceptable, he sums up his conclusions in a sort of anthem:—

> "Every cubic millimetre of the universal ether of space must possess the equivalent of a thousand tons, and every part of it must be squirming internally with the velocity of light."

It will be seen that the book is in substance a restatement of the author's most recent speculations, in which, of course, he stands by no means alone. If it somehow fails to do full justice to these, and if in some respects the original papers in the *Philosophical Magazine* and elsewhere will probably be found by many to be really easier reading, the auspices under which it is brought out are no doubt partly accountable. The general reader, even if he is disposed to take most things on trust, and does not adopt the critical attitude which the author would himself welcome, will at all events learn to understand the admiration which the scientific world feels for the genius and unflagging spirit with which a most difficult as well as stupendous theme is repeatedly essayed.

H. L.

NEW METHODS OF WEATHER FORECASTING.

Nouvelle Méthode de Prévision du Temps. By Gabriel Guilbert. Pp. xxxviii+343. (Paris: Gauthier-Villars, 1909.)

MONSIEUR GABRIEL GUILBERT, the winner of the prize offered in 1905 by the Société belge d'Astronomie, de Météorologie et de Physique du Globe, for the most successful short-period forecasts of weather, has published in book-form a detailed exposition of the principles underlying his method. He introduces two new principles into the art of weather forecasting, which, so far as we are aware, have not been stated explicitly by any other writer on this subject. First, he invites us to compare the force of the wind at the surface as observed at the various stations contributing to our daily weather reports with the barometric gradient at sea-level. If in any region the observed wind forces are markedly in excess of the normal for the prevailing gradient, a surge of high pressure in the direction of the gradient may be looked for, and *vice versa.* His definition of the word "normal" is entirely conventional. It is based on comparisons made by Clement Ley, Sprung, Köppen, and others, and is that the number expressing the wind force on the Beaufort scale shall be twice that expressing the gradient in millimetres of mercury per degree (111 km.). It follows from this general principle that a depression which is surrounded on all sides by winds in excess of the normal will fill up, whereas a depression surrounded by winds in defect will grow deeper. If the defect is great, a depression of small intensity will develop into a violent storm centre. A depression round which the distribution of wind force as compared with the prevailing gradient is unsymmetrical will move towards the region of "least resistance," *i.e.* the region where the winds are most conspicuously in defect. In identifying the region of least resistance the second principle is also used. It is based on the conception of "divergent" winds. Any wind which has a component directed away from a centre of low pressure is divergent for that centre, and as such marks a region of low resistance to its advance. Generally speaking, the greater the "divergence" the less the "resistance." Strong northerly or north-westerly winds to the eastward of a depression are looked upon as an extreme case of divergence, and as a sure sign of a rapid advance of the depression.

M. Guilbert proceeds to elaborate no fewer than twenty-five rules for forecasting which for the most part follow more or less directly from the two fundamental principles. Their application is illustrated by a large number of examples, taken mostly from cases when the forecasts issued by the Bureau at Paris proved incorrect.

So far as M. Guilbert is concerned, both principles must be looked upon as a direct result of the careful scrutiny of weather maps; they are entirely empirical, and no attempt is made to justify them from general dynamical considerations. Since the book has been in our hands, we have watched the charts published in the Daily Weather Report, and have noticed occasions on which the application of the first principle would apparently have been useful. On other occasions we have found difficulty in applying the rule. On many maps there are, within one and the same meteorological region, winds which are, some in excess, others in defect, of the normal. M. Guilbert gives no instructions as to how to proceed in such cases.

The principle of the "divergent" wind is not likely to be accepted without qualification in the form in which it is put forward. M. Guilbert insists very strongly that a single conspicuously divergent surface wind (observations on mountains or at high levels are expressly ruled out as not being comparable with the surface gradient) must be regarded as an almost infallible indication of the early advance of a depression. Objections based on the argument that surface winds are very liable to be influenced by local conditions are brushed aside. Among the examples quoted in the book there are many instances of surprisingly daring and successful predictions, some apparently *ex post facto*, others attested by stamped postcards as being genuine forecasts made before the event. We are, however, entitled to ask whether the rules might not lead to equally daring but unsuccessful forecasts? Nearly 100 examples are quoted; the number is large, but so is the number of charts from which the selection is made, and it is to be supposed that M. Guilbert, whose style often suggests counsel's address to the jury rather than the judge's summing up, has picked out the cases which best illustrate his points. No doubt he could produce many more instances if called upon to do so, but the multiplication of selected examples does not carry conviction. Before passing judgment we must hear counsel for the other side, who may be able to bring forward a similar number of cases at variance with the principles advanced. M. Guilbert has run up against the old difficulty of expressing his hypothesis in such a manner that it can be tested by an appeal to measurement. The relation between the observed wind velocity and the gradient should lend itself to numerical treatment, seeing that both quantities are the object of regular observation and measurement.

The book is accompanied by a preface by Prof. Bernard Brunhes, the director of the observatory on the Puy de Dôme, who acted as reporter on the occasion of the competition at Liége. In a supplement M. Brunhes points out that M. Guilbert's rules are consistent with the results deduced by Lord Kelvin and Bjerknes for the action of a steady current on a vortex, and describes some laboratory experiments of his own illustrating the phenomena.

MEDICAL EMBRYOLOGY.

Text-book of Embryology. By Dr. Frederick R. Bailey and Adam M. Miller. Pp. xvi+672. (London: J. and A. Churchill, 1909.) Price 21*s.* net.

THIS bulky volume is the third American text-book of embryology that has appeared in recent years. Like Prof. Heisler's work, of which a revised edition was published two years ago, it is addressed primarily to students of medicine and anatomy, being, in fact, based upon the course in embryology given at the medical school of Columbia University. Consequently it differs in its style of treatment from Prof. Lillie's "Development of the Chick," which is apparently intended for zoological students beginning embryology; and whereas Prof. Lillie confines his attention almost exclusively to a single type, and never passes outside the class Aves, the authors of the present volume, although dealing more particularly with human development, have aimed at treating the subject from a comparative standpoint, believing this to be the most efficient way of teaching it. With this opinion most teachers of biology must surely concur. It is satisfactory to note also that the physiology of the developmental processes is not entirely passed over. Thus, in an excellent chapter on the nervous system contributed to this volume by Dr. Oliver S. Strong, the author has been able to include much physiological matter which usually finds no place in a text-book of embryology.

In the second chapter a section is devoted to ovulation and menstruation and the relation which subsists between these processes, but it is to be regretted that the comparative method which is so successfully followed in other parts of the work is not extended to the problems dealt with here. That menstruation in the Primates is the physiological homologue of the prodestrum in the lower Mammalia, and that in the latter ovulation occurs normally during œstrus, are now generally accepted facts, the recognition of which has removed many apparent difficulties which used to perplex the older writers.

Messrs. Bailey and Miller quote Leopold's observations, but they omit to mention that the later investigations of Heape, Sobotta, and others have thrown a new light on the subject. In this connection reference may be made also to the recently published memoir by Bryce and Teacher, whose conclusions in regard to the usual time for ovulation in man are in general agreement with those arrived at by investigators of the sexual processes in the lower Mammalia.

The authors state that the discharged follicle "becomes organised by ingrowth of vessels from the theca to form the corpus hæmorrhagicum" (p. 32). The latter name is more correctly applied to the follicle when it contains a blood-clot, as happens frequently (but by no means invariably) after ovulation, and the term is used in this sense on a later page (p. 413). The cells of the membrana granulosa do not actively proliferate before becoming luteal cells, as stated here (pp. 32 and 413), but undergo a process of simple hypertrophy. Cell-division in this layer is extremely rare after ovulation has taken place.

The authors lay due stress on the fact that the ovaries are ductless glands, not only physiologically and anatomically, but also developmentally. On a later page (p. 437) they make the statement that congenital absence of the ovaries may occur without defects in the other generative organs. We do not know on what authority this observation is cited, and in view of the fact that the uterus undergoes atrophy after ovariotomy (or remains infantile if the operation is performed in early life), the statement seems on the face of it unlikely.

The question as to the determination of sex is discussed at some length, and the recent observations of Wilson, McClung, Morgan, and Correns are referred to. Some of the older experiments on feeding caterpillars, tadpoles, &c., are also described, but the authors do not mention that the evidence derived from these has been to a large extent invalidated by the recent work of Cuénot, Kellogg, and others.

The book is divided into two parts, the first dealing with general development, including the development of the external form of the body, while the second is devoted to organogenesis. The sections at the ends of the chapters, treating of the origin of malformations and developmental anomalies, are a special feature. Moreover, there is a final chapter on teratogenesis, in which the views of Beard, Mall, and others are duly referred to. Suggestions for practical work, with descriptions of the necessary technique, are also included.

There are a few minor errors. For example, on p. 115, "Fig. 107" is a misprint for "Fig. 108," and on p. 416 "Girou" is wrongly written "Giron."

Among the more noteworthy omissions are absence of reference to the "phylogenetic law" (commonly but erroneously called the law of von Baer), excepting for a passing mention on p. 387, Miss Lane Claypon's work on the origin of ova from ovarian interstitial cells during adult life, Herring's researches on the development of the pituitary, and Gaskell's work on "The Origin of Vertebrates," which, with all its wealth of detail and illustration, morphologists cannot afford to ignore. However, much valuable and important matter is included, and the volume as a whole forms a useful addition to the literature of medical embryology.

FRANCIS H. A. MARSHALL.

FUNDAMENTAL PROBLEMS OF PSYCHIATRY.

Modern Problems in Psychiatry. By Prof. E. Lugaro. Translated by Dr. David Orr and Dr. E. G. Rows. Pp. vii+305. (Manchester: University Press, 1909.) Price 7*s*. 6*d*. net.

THIS translation will be welcomed by those who are interested in the study of mental disease, but have been unable to read the original Italian work. The book is intended to pass in review the chief fundamental problems which present themselves to the student of psychiatry. As the author states in his preface, the latter must be a man of extensive knowledge, since his study carries him into the most difficult branches of anatomy, physiology, pathology, psychology, sociology and even criminology. The author also hints that one object of his book is to justify the claim of psychiatry to a place among the sciences and by the side of general medicine, and to remove from the public mind the existing prejudice against the study of mental disorders. The work is, however, surely too learned a disquisition to engage the attention of an ordinary layman. We regret to find that the author himself draws a distinction between physicians and "alienists" (p. 71), as if so-called "alienists" were not physicians; yet we understand that even in Italy psychiatry is a well-recognised branch of medicine.

While admitting that it is still necessary at the present day to define clearly one's position in relation to metaphysical doctrines, we consider that Prof. Lugaro is too respectful to effete hypotheses of the nature of mind in devoting so much space to dismissing them. His final attitude is that he accepts the external world as an existing reality independent of our experience of it; while consciousness he regards as coinciding, perhaps identical, with experience; whether the experience be that of the philosopher, peasant, child or brute. This mode of regarding consciousness he designates "primitive realism."

The book as a whole strikes one as the work of a pathologist and anatomist with but limited clinical experience. The chapters on anatomical, physiological and allied problems should claim the attention of every asylum physician; those on pathogenesis and etiology are not so strong, but they repay perusal.

In the anatomical section the researches of Ramon y Cajal, Nissl, Brodmann and Vogt on the histology of the cortex are passed in review, but we note with regret that the excellent work of Campbell is not even mentioned. Similarly, in the physiological section we regard it as an important omission that no reference is made to Sherrington's researches.

Prof. Lugaro is a believer in the utility of hypotheses. "If a hypothesis starts from assured facts and involves no errors of reasoning, it has as much value as the observation from which it takes origin," and "even the observations on which it is based acquire greater force." Accordingly we are here and there treated to a useful hypothesis. For example, the fact that the first collaterals from the axon of a cortical projection neuron are directed back to the cortex means for Lugaro that neighbouring neurons are stimulated to participate in the action of the first neuron, and that the function of these particular collaterals is to diffuse stimuli.

The superficial layer of the cerebral cortex is regarded as associational in function, the middle layer as motor, and the deep layer as sensory. It appears that the very deepest layer of the cortex, the destruction of which gives rise to the remarkable syndrome known as dementia precox, is normally developed much more in man than in lower animals, even the highest apes. We note, by the way, that the author regards the neuroglia as an anti-toxic substance, since it reacts more than the true nervous tissue to toxic substances.

The author very properly decries, on the one hand, the superficial methods of examination of insane patients as practised in most asylums and, on the other, the systematic examination by a hundred or more tests employed by certain enthusiastic plodders. The first is desultory and can never advance the science of psychiatry one whit, while the second is unpractical. Kraepelin's methods meet with the professor's approval.

On p. 64 Lugaro expresses the view that the manifestations of insanity at times defy comparison with normal processes, but here we would accuse him of failing to see below the surface; a normal instinct may be compared with its distorted self in disease, and any normal mental function may fitly be compared with its absence where such absence constitutes a positive symptom.

The author's views respecting heredity are rather heterodox. He starts with the premiss that the tendency of heredity is to improve the race, and appears to conclude therefrom that heredity is an over-estimated factor in the causation of insanity. He has some difficulty in rejecting the possibility of acquired characteristics being transmitted but, after a long discussion of the matter, appears finally forced to do so.

Private asylums receive some severe criticism. These institutions in Italy are apparently in a parlous state; but many in England come well beneath the ban, and this part of the book should not be read in a pharisaical mood.

The work should be on the shelf of every pathologist and asylum physician; it is thoughtful, suggestive and well written. The translation also is excellent, but there are a few infinitives that might with advantage be unsplit when the next edition appears, as it undoubtedly will.

THE AUTOBIOGRAPHY OF N. S. SHALER.

The Autobiography of Nathaniel Southgate Shaler, with a Supplementary Memoir by his Wife. Pp. x+482. (Boston and New York: Houghton Mifflin Company, 1909.) Price 16*s.* net.

THE keynote of this book is to be found in its final lines, written to Mrs. Shaler by Prof. G. H. Palmer:—

"How large your companionship with him was your words in this volume, and elsewhere, show. Happy woman to have been so blest, and happy we who were allowed to know you both!"

The book is the outcome of a personal relationship, which pervades it, but which does not obtrude upon the reader. We are spared the emotional and sometimes spiteful passages which are supposed in so many biographies to add vitality to the story of a married life. We gather instead a sense of peace, such as comes from long-continued good work, jointly and perseveringly performed. But we do not get to know Shaler through these pages as generations of Harvard students knew him. Prof. W. H. Hobbs, indeed, wrote two years ago:—

"It would be necessary to secure a composite of the memory picture of literally thousands of students in order adequately to present the characteristics of this truly remarkable man to one who had never known him."

It was the man himself, a fighter from his youth, vigorous, virile, yet painstaking in a high degree, that established his claim on others, rather than the work he did. Hence his autobiography, which ends in 1861, and the modestly entitled "supplementary memoir," which covers the remaining forty-five years of his life, will be read with most pleasure by those to whom passage after passage will recall some familiar trait, some habit, perhaps some manner of speech, impossible to set down in print.

As an account of a life spent in transition times, when the easy-going, slave-tended society of the south was about to organise itself for a strife of heroes, the autobiography leaves us somewhat cold. We have useful glimpses, however, of Louis Agassiz, then dominating the natural science course at Harvard, and the anecdotes of his methods as a curator and an examiner (pp. 93–104, and 189–92) will please those called to similar duties. Young Shaler, studying fishes under his care, was left to describe what he could observe for himself, and was merely told when he was wrong; whereupon he would begin again, and so on, until his master found that the results tallied with his own. The impression made by Agassiz in denouncing the Darwin-Wallace school is well shown by the story of his pupil Stimpson (p. 129), who, when convinced that he had found intermediate links among molluscan species, ground "one of these vexatious shapes" to powder with his heel, remarking, "That's the proper way to serve a damned transitional form."

Shaler, of course, soon accepted the new views. He studied zoology practically, by dredging, fishing, and shooting, though he much disliked killing animals; and he was thus engaged, in his twentieth year, when the men of his native State, Kentucky, had to decide for or against the Union. The movement in the south was regarded as desultory; even if it continued, it was not going to reach Kentucky for some years; and Shaler set off with Hyatt in 1861 for a sail of several months about the mouth of the St. Lawrence. This peaceful campaign, with its scientific aims, involving a rough-and-tumble life on a small boat, prepared him for many a future struggle.

Shaler returned from it to find even neutral Kentucky divided within itself; and soon, though the chief actor tells us nothing of it, "Shaler's battery" became known upon the Union side.

Shaler married in 1862; but his wife refers us to his various writings on the war, and quotes very little from letters written to her from the field. The advance of Rosecrans on Nashville left Kentucky outside the crash of armies, and no echo reaches us of the bitter days round Chattanooga. It is of far more importance to Mrs. Shaler to record—and this was probably the feeling of all who knew her husband—that in 1864 Shaler was appointed assistant in palæontology in Harvard University. In 1869 he became professor of this subject, when only twenty-eight; then he was made professor of geology; and in 1891 he was chosen as Dean of the Lawrence Scientific School. Even his position from 1874 to 1880 as Director of the Geological Survey of Kentucky did not break his connection with the development of Harvard. For more than forty years, down to his death in 1906, he was one of the most familiar figures in the courts of the university.

Chapter xix., which deals with a visit to England, contains characteristic mention of Tyndall, and of several English geologists. Here, as in other places, some proper names have gone astray. The Rev. Mr. Simons of p. 256—have we not made the same rural journey to enjoy a meeting at his gate?—must surely be the late W. S. Symonds, the friend of all naturalists in the Midlands. Elsewhere we have "Renivier," "Guinitz," "Geoffrys" for Jeffreys, and "Marais," as we may presume, for "Marey." These slips result from copying out of diaries, where the incidents of the day have been set down. The incidents thus recorded, page after page, seem rarely of value in themselves; yet it is clear that we may end this notice much as we began. To those for whom the book is written, those whom Shaler had helped or stood by as a friend, nothing about Shaler will seem unworthy to be expressed. GRENVILLE A. J. COLE.

MATHEMATICAL TEXT-BOOKS.

(1) *Geometry for Beginners.* By C. Godfrey and A. W. Siddons. Pp. x+79. (Cambridge: University Press, 1909.) Price 1s.

(2) *The School Geometry.* Parts i. and ii. By W. P. Workman and A. G. Cracknell. Part i., pp. viii+248. Part ii., pp. viii+(233–383). (Cambridge: University Tutorial Press, Ltd., 1909.) Price 2s. each part.

(3) *Coordinate Geometry.* By H. B. Fine and H. D. Thompson. Pp. viii+300. (London: Macmillan and Co., Ltd., 1909.) Price 6s. 6d. net.

(4) *Exercise Papers in Elementary Algebra.* By the Rev. E. M. Radford. Pp. viii+112. (London: J. M. Dent and Co., 1909.)

(5) *Problem Papers in Mathematics.* By R. C. Fawdry. Pp. vii+240. (London: Macmillan and Co., Ltd., 1909.) Price 4s. 6d.

(1) IN the light of the experience gained in the last eight years or more, it is now possible to estimate, with considerable accuracy, the effect of the numerous changes which have been made in the methods of teaching elementary geometry. The circular issued by the Board of Education last March contains a report on this subject which is well worth careful perusal. The central feature of the modern movement has been an attempt to familiarise the pupil with the fundamental concepts by experimental methods, before providing him with formal proofs. It is now suggested that this experimental stage, by being made more systematic, should *replace* the first part of the present deductive course. The properties of parallel lines and congruent triangles possess a characteristic which pertains to few, if any, of the later theorems. Once a pupil clearly apprehends their significance, which is possible only by experimental work, he is convinced with absolute assurance of their truth; and this very fact only serves to increase the difficulties which surround the formal proof. In the words of the circular,

> "to commence the subject by proving what seems to need no proof is a safe way to make boys think that the whole subject is artificial and unreal. It is much better to begin Euclidean, that is, deductive proofs at the point where their necessity can be appreciated—that is after these fundamental propositions—and where, therefore, the proof is a natural process, not subject to arbitrary or artificial rules."

If then these base-theorems are incorporated in the experimental stage, and if at the end of this course those fundamental concepts, which have been thereby assimilated, are allowed to be assumed without formal proof, the course of deductive geometry will open with the properties of areas of triangles and parallelograms, and continue with theorems on the circle. In this way, at the end of his first year, a pupil will have covered as much ground as at present is covered, in the majority of cases, only after two or three years.

The present excellent little volume has been compiled to cover the complete experimental course outlined above, and it follows in every respect, save one, the suggestions made by the Board of Education. It is, however, advised in the circular that riders should be excluded entirely from the experimental stage; although in this way time may be saved and greater emphasis placed upon the fundamental theorems, yet simple riders so frequently serve to illustrate a theorem, and, moreover, form a valuable introduction to the future deductive course, that we are firmly convinced that the authors are right in inserting a large number of easy deductive examples in the text. We have developed these considerations at some length, because we consider that the change now advocated is likely to exert a profound influence on the teaching of geometry, and that the more it is considered in all its bearings, the more advantageous it will appear.

(2) This is an abridged edition of the authors' work, entitled "Geometry: Theoretical and Practical," published about two years ago. In the present book a certain amount of theory which may be fairly considered to be beyond the range of the average schoolboy has been omitted. The sequence adopted in the theoretical course is that of the Cambridge syllabus. Part i. contains the substance of Euclid books i., iii.; part ii. that of books ii., iv., vi., together with those

modern extensions, such as harmonic ranges and coaxal circles, which now form a customary part of the school course.

(3) In this treatise the elements of coordinate geometry are presented in a compact form. The first twelve chapters are devoted to the treatment of the line, circle, conic, and other curves, while the remaining six deal with the line in space and the surfaces of the second degree. The experience of the authors has led them to introduce a number of changes in the order of development of the subject. The equation of the straight line is given, before the customary work on lengths and areas; they advise the student to read the chapter on the parabola before that on the circle, thereby enabling him to see at an early stage how analytical methods may be used to obtain properties which are new to him. All mention of pole and polar properties is deferred until after the treatment of the general conic, and the application of Cartesian methods to the investigation of loci is postponed to the final chapter of the first part of the book.

The section on solid geometry, while omitting the more complicated analytical formulæ, is sufficiently thorough to enable the student to attack with success any problem on the geometry of the conicoid of a straightforward character. There are numerous exercises and diagrams. In every respect this book is admirably suited to meet the needs of those who are reading the subject for the first time.

(4) The range of work covered by Mr. Radford's useful book includes the binomial theorem and the exponential and logarithmic expansions. Quadratic equations and graphical solutions are introduced at the start, and logarithms appear at an early stage. There are also ten book-work papers.

(5) The papers set in recent examinations conducted by the Civil Service Commissioners have included a number of problems of a much more practical character than are to be found in the ordinary academic text-book. That this type of question is both stimulating and of real educational value is beyond question, but up to the present there has been no convenient collection of problems of this character. Mr. Fawdry's book now supplies exactly what is wanted. Primarily, it is intended for army candidates and students in technical colleges, but many of the papers contain practical questions of considerable intrinsic theoretical difficulty, and may therefore profitably be set to boys preparing for entrance college scholarships. A comprehensive set of revision papers adds materially to the utility of this first-rate book.

OUR BOOK SHELF.

Ant Communities and How they are Governed. A Study in Natural Civics. By Dr. H. C. McCook. Pp. xvii+321. (New York and London: Harper and Bros., 1909.) Price 7*s.* 6*d.* net.

FOR thirty-two years Dr. McCook has devoted much time and attention to the habits of American ants, and has published many popular works on the subject, in addition to the two large works on "The Agricultural Ants of Texas" and "The Honey Ants of the Garden of the Gods." In the present work, which is based chiefly on his own original observations, he discusses the conditions of ant-life from a popular standpoint; and his sixteen chapters deal with such subjects as fraternal confederacies, nesting architecture, engineering, feeding the commune, language, government, dependents, war, aliens, aphis herds, slave-making, sanitation, &c.

Britain is very deficient, both as regards number of species and number of individuals; but the American species are more numerous, and the size of nests and communities of many species is almost incredible. Thus Dr. McCook writes:—"The large conical nests of the mound-making ants of the Alleghanies, *Formica exsectoides* vary in size from newly-begun colonies a few inches high to mature hills, measuring thirty-seven feet in circumference at the base, though rarely more than three feet high. They occur in groups, and in one site near Hollidaysburg, Pennsylvania, within a space of fifty acres, the writer counted seventeen hundred well-developed mounds. At two other localities in these mountains, similar groups were observed even more thickly placed. At "Pine Hill," about thirty acres were occupied, of which five were found to contain two hundred and ninety-three mounds, an average of fifty-nine to the acre, or eighteen hundred for the whole section. At "Warrior's Mark," another large settlement of nearly two hundred hills was visited. Experiments made in the Hollidaysburg group proved that all therein formed substantially one community, in complete fellowship, although the individual mounds appeared to be conducted independently" (pp. 3–5).

Dr. Forel's comment on these observations is:—"These ant kingdoms have in all probability a population of two hundred to four hundred million inhabitants, all forming a single community, and living together in active and friendly intercourse" (quoted at p. 8).

Again, with reference to the cutting ants of Texas, we read:—"A planter, in order to get rid of the depredations of an immense commune near his residence, had set his men to dig it up and utterly root it out. In order to reach the central nest he had traced the ants from a tree inside his home premises, which they had stripped of leaves, to a point six hundred and sixty-nine feet distant. The nest occupied a space as large as a small cellar, the lowest and main cave being as large as a flour-barrel. In this central cavern were great numbers of winged males and females, and innumerable larvæ and workers. From this point radiated the various avenues over which the leaf-cutters marched on their raids" (p. 64).

We could quote equally interesting passages from almost every page of this fascinating volume; but before concluding, we may note that Dr. McCook attaches great importance to the sense of smell in ants.

The numerous text-illustrations are of unusual excellence.

Sextant Errors. By Thos. Y. Baker. Pp. 32. (London: J. Griffin and Co., 1909.) Price 1*s.* net.

MR. BAKER has supplied a very excellent shillingsworth for those who have occasion to use the sextant and wish to understand it properly. Every text-book gives the simple theory of the instrument, and the more ordinary adjustments and tests for errors are generally enough understood, but when the complete theory of an astronomical instrument, worked out on the supposition that no part is quite perfectly made, is required, then only such elaborate books as, for instance, Chauvenet may be turned to with confidence. It will be a great convenience to the sextant user to find in this little book complete demonstrations, free from the usual omission of steps, unnecessary for the writer of the book, but sadly needed by the reader, of the important errors, with specially prepared tables to facilitate calculation.

The extreme importance of the collimation error and its surprising possible magnitude are pointed out, and a very neat way of ascertaining if the telescopic axis is perpendicular to the index mirror when the arm is suitably turned is described, but it is unfortunate that this is not available in all sextants as made.

One fault must be insisted on. The use of the signs ′ and ″ for feet and inches instead of the abbreviations ft. and in. is bad enough when used by engineers, but then it is rare that there is fear of confusion. The author, however, gratuitously causes confusion in a book which is bristling with the signs ′ and ″ in their proper meaning by using the symbol ″ for inches even in the same sentence with ″ in its proper meaning. It is to be hoped that this and one or two typographical errors will be corrected in a future edition.

C. V. B.

The British Journal Photographic Almanac, 1910. Edited by George E. Brown. Pp. 1320. (London: Henry Greenwood and Co.) Price 1*s.*

THE present issue of this very useful volume is drawn up on the same lines as those of its immediate predecessor, and its contents are of the usual essence of photographic matter on all topics, which makes it such a valuable *aide mémoire* to the working photographer. Commencing with the usual calendar, which begins on p. 407, and not on p. 447 (as it is incorrectly indexed, by the way), there follows the useful directory of photographic societies and bodies. An interesting chapter on lens calculations by mental arithmetic, written by the editor, precedes the large section on the epitome of progress by the same authority. This latter portion is always one of the chief contributions to the volume. Then follows a description of the recent novelties in apparatus, which occupies nearly 100 pages. Formulæ for the principal photographic processes, the developing formulæ of the principal plate and paper makers, miscellaneous information, and the usual large number of valuable chemical, exposure, optical, and other tables, bring the volume to a conclusion.

Another feature of this publication, and one which is so often referred to by those who have the book in their possession, is the excellently indexed mass of advertisements in which the main text of the book is sandwiched.

The volume should find its usual place in every photographer's library.

Outlines of Bacteriology (Technical and Agricultural). By Dr. David Ellis. Pp. xii+262. (London: Longmans, Green and Co., 1909.) Price 7*s.* 6*d.* net.

THE general plan of this book is excellent, but we doubt if the various subjects are dealt with in sufficient detail to render the book of much practical utility to the student. To attempt to deal with disease-producing organisms and all the technical applications of bacteriology in 260 short pages is an impossible task if anything more than general principles is to be considered.

The contents of the book include the general morphology and biology of the bacteria, a subject to which the author has himself contributed, sterilisation, pathogenic bacteria, sulphur and iron bacteria, preservation of food products, nitrification, fermentation and ferments, and their industrial applications (*e.g.* beer, butter, cheese, tanning, tobacco, &c.), and sewage disposal.

Unfortunately, a number of errors disfigure the text. Thus on p. 109 a classification of proteids is given in which one class is termed "amyloids" and is stated to be insoluble in gastric juice, globulins are said to be soluble in dilute acids, and casein is given as an example of a derived albumin, and is said to be soluble in dilute acids. A number of mistakes also occur in the section dealing with pathogenic organisms. In the section on the preservation of food-stuffs by heat, while canning is mentioned, there is no reference to the sterilisation or the pasteurisation of milk. The names of plants yielding flax, hemp, jute, &c., are not correctly given, and on p. 245 a paragraph dealing with the *Bacillus enteritidis* of Gärtner is hopelessly wrong.

The book is clearly printed, and illustrated with a number of figures. Many of these are very diagrammatic and drawn to no scale, so that the reader sees the anthrax bacillus and influenza bacillus depicted about the same size, which is somewhat misleading.

R. T. HEWLETT.

A Descriptive Catalogue of the Dobrée Collection of European Noctuae. Compiled by H. B. Browne. Hull Museum Publications, No. 63. Pp. xv+156. (Hull: A. Brown and Sons, Ltd., 1909.) Price 1*s.* net.

THE late Nicholas Frank Dobrée, of the New Walk, Beverley, who died in 1908, at the age of seventy-seven, formed a very valuable collection of Palæarctic Noctuæ between the years 1871 and 1888, which he subsequently presented to Hull Museum, on the understanding that a complete catalogue should be published. We presume that it will be preserved intact, for we are convinced that special collections of all kinds, whether literary or scientific, are of far greater permanent value whenever it is possible to preserve them thus, than when they are (sometimes unavoidably) dispersed, or even broken up to be incorporated with larger collections. The collection includes longer or shorter series of 654 species, more than 300 named varieties and aberrations, and 720 specimens of preserved larvæ. These are contained in forty-two cabinet drawers, and Mr. Browne has carefully noted the origin of every specimen according to Mr. Dobrée's note-books, and added short descriptions of a large number of aberrant specimens, named or otherwise. The work is of much importance to all students of the interesting group of moths of which it treats.

The Human Race: its Past, Present, and Probable Future. An essay by J. Samuelson. Pp. xii+192. (London: Swan Sonnenschein and Co., Ltd., 1910.) Price 3*s.* 6*d.* net.

IN part of this small volume is summarised the whole history of the human race—man's origin and material progress, the history of his vices and virtues, and of his mental, social, and political development. That such a summary must be very superficial is only to be expected, and the author claims very little for it, but hopes "that it will at least stimulate inquiry and serious study on the part of youths about entering life." Its chief fault appears to us to be that there is no clear distinction drawn between changes in man himself and changes in his surroundings. Thus, for example, under the heading "Man's Mental Progress" are catalogued a number of discoveries and inventions, such as the spectroscope and telephone, which are not evidence of mental progress at all if one takes the term to mean improvement of mental powers. It is also to be regretted that, although the author appears to be a believer in evolution, no mention is made of heredity as a factor possibly affecting the history of mankind.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Heat developed during the Absorption of Electricity by Metals.

IN 1901 (O. W. Richardson, Camb. Phil. Proc., vol. xi., p. 286) one of the present writers showed that the phenomena attending the emission of negative electricity by hot metals could be explained on the assumption that the electrons which, on the electron theory of metallic conduction, move freely inside the metal attain sufficient kinetic energy at high temperatures to enable them to overcome the forces tending to keep them inside the surface and so escape. From the way in which the thermionic current varied with the temperature of the metal it was shown that the difference in the value of the potential energy of an electron when outside and when inside a metal could be calculated. Somewhat later (O. W. Richardson, Phil. Trans., A, vol. cci., p. 497) it was shown that the existence of this difference in the potential energies would involve a loss of thermal energy by the substance when the electrons were being given off, and it was pointed out that this effect would increase very rapidly with the temperature, so that at sufficiently high temperatures the loss of energy due to this cause would be greater than that arising from thermal radiation. An effect of this character has recently been discovered by Wehnelt and Jentzsch (*Ann. der Physik*, iv., vol. xxviii., p. 537).

Another consequence of the existence of this difference of potential energy is that when electrons possessing negligible kinetic energy pass into a metal an amount of heat should be liberated which is equal in magnitude to the difference in the potential energy for each electron multiplied by the number of electrons entering the metal. Experiments which have been carried out by the writers show that this effect exists, and is of the expected order of magnitude.

The method adopted was to cause the electrons emitted by two hot osmium filaments to flow on to a grid of fine platinum wire, which acted as a bolometer, and was placed in one arm of a double Wheatstone's bridge. The double bridge arrangement enabled the galvanometer to be balanced for the thermionic current into the bolometer in each experiment. The change in the resistance of the bolometer per unit thermionic current was measured when different voltages were maintained between it and the negative ends of the filaments.

In order to standardise the bolometer a known variation of current through it was produced, and the resulting change of resistance due to heating measured. By making use of this datum the energy received by the bolometer per unit thermionic current can be expressed in terms of the fall of potential which the electrons would have to undergo in order to produce the observed effect. The value thus obtained may be denoted by the "effect in volts."

When the effect in volts E is plotted as ordinate against the negative potential of the negative end of the filaments V as abscissa, the relation between them appears to be a linear one. The line, however, which is obtained does not intersect the axis of ordinates at $E=0$, but in the neighbourhood of $E=3$ volts, showing that when the electrons fall through no difference of potential due to the field they are still able to produce a heating effect equivalent to that due to the energy they would have received in falling through a difference of potential of about 3 volts. Inasmuch as Richardson and Brown (*Phil. Mag.* [6], vol. xvi., p. 353) have shown that the natural kinetic energy with which the thermions are emitted corresponds to only about 1/30 volt, the conclusion is inevitable that there is a liberation of potential energy when the electrons enter the metal comparable with that which would be acquired by falling through a difference of potential of about 3 volts.

Experiments have, so far, been made with applied potentials varying from $+2$ to -9 volts, the potential drop along the filaments due to the heating current varying from 3 to 3·7 volts. Changes are now being made in the experimental arrangements which, it is believed, will lead to greater accuracy of measurement. It seems likely that, owing to certain defects in the present apparatus, the values which have so far been obtained are somewhat too low.

Malaria and Ancient Greece.

IN his scholarly "Malaria and Ancient Greece," reviewed in NATURE of December 16, 1909, p. 192, Mr. Jones has apparently overlooked what seems to be, though modified for dramatic purposes, a description of an acute attack of ague, *i.e.* that given by Sophocles of the sufferings of Philoctetes in his play known by that name. Here, just as he is about to accompany Neoptolemus to the ships, Philoctetes is seized with a sudden attack (line 730). He recognises the prodromal symptoms of what he describes to Neoptolemus as a recurrent attack of his malady (*ἥκει γὰρ αὕτη διὰ χρόνου*, line 758). The attack appears to be ushered in with pain or discomfort (line 730) and shivering (735). The symptoms become increasingly acute (*καί τι προσδοκῶ νέον*, 784) until they become almost unendurable (790). Soon, however, from previous experience, Philoctetes can foretell that the worst is over (808), and that the attack will pass away during the sleep which always supervenes. *λαμβάνει γὰρ οὖν ὕπνος μ', ὅταν περ τὸ κακὸν ἐξίῃ τόδε*, 766.

Later on, as he is falling asleep, Neoptolemus directs the attention of the Chorus to the profuse perspiration which bathes his body (823). The periodicity, suddenness, and ingravescence of the symptoms, the sleep and sweating followed by a passing feebleness on waking (880), present a clinical picture the vividness and truth of which are not surpassed in any literature. The congeries of symptoms in this description must be based upon actual experience of disease. It will, of course, be urged that Sophocles makes all the symptoms dependent upon the uncured wound in the heel caused by the snake-bite at the shrine of Chryse. Here there need be, however, no difficulty in the acceptance of the ague theory, for this would be in full accord with the accepted pathology of the period. The Greek physicians were probably well acquainted with the characteristic results of non-fatal snake-bite—the pain, sloughing with foul discharge, and delayed healing.

Without attempting to labour the point further, from a strictly clinical point of view the imposition of a malarial infection upon a chronic condition such as that described would, without doubt, give rise to periodic exacerbations of the inflammatory conditions. This is probably the explanation of the statement of Hippocrates quoted by Arndt (*cp.* Jebb, *Philoctetes*, p. 241) that the "ulcers become especially inflamed on these alternate days."

The *Philoctetes* was performed in 409 B.C., just when, according to Mr. Jones's theory, malaria was becoming widely disseminated through Greece, and nothing would be more natural than that Sophocles, in his wish to draw the sympathies of his audience to his long-suffering hero, should represent him as wracked with all the horrors of the new and strange disease, which appeared to lend themselves peculiarly to his purpose. There can scarcely be a sight more pitiable than that of a person in an acute paroxysm of malaria.

It is much to be regretted that the loss of their respective plays prevents a comparison with the manner in which Æschylus and Euripides treated the subject. That Sophocles had a keen clinical grasp of the salient features of disease is noticeable in his description of the Acute Delusional Insanity of Ajax—a description of a form of mental aberration which is extraordinarily true to nature, and one which from a clinical standpoint far surpasses the delineations of madness by Shakespeare, as might indeed be expected from a consideration of the relative positions of medicine as a science at the times of the respective poets.

Birmingham.

An Example of Spurious Correlation.

If I am not mistaken, the first method of forecasting the summer season proposed by Mr. A. B. MacDowall in NATURE of September 16, 1909 (vol. lxxxi., p. 335), is based upon a spurious correlation. If we take a series of departures from normal of a meteorological element and tabulate the sums of consecutive groups of thirty, there will always be a relationship between these sums, although the original departures may be entirely independent, and hence the relationship between the sums cannot be utilised for forecasting an individual term of the original series. That such sums of independent departures are not independent may be seen in the following way. If we denote the original independent departures by d_1, d_2, . . ., and the sum of thirty quantities beginning with d_p by s_p, the correlation coefficient between such quantities as s_p and s_{p+1}, as given by statistical methods, will be the mean value of a long series of products $s_p\, s_{p+1}$ divided by the product of the square roots of the mean values of s^2_p and of s^2_{p+1}. Now as d_p, d_q are independent the mean value of the product $d_p\, d_q$ will be zero; and it is easily seen that the correlation coefficient in question is the mean value of $(d^2_{p+1}+d^2_{p+2}+ \quad +d^2_{p+29})$ divided by the product of the square roots of the mean values of $(d^2_{p+} \ldots +d^2_{p+29})$ and of $(d^2_{p+1}+ \quad +d^2_{p+30})$; if we denote the mean value of d^2_q by m^2, this becomes $29m\,/30m^2$, or 29/30. Thus the thirty-year sums of independent annual departures will tend to vary closely together, and the dots in a diagram like that of p. 335 would tend to lie on a straight line.

The relationship actually found by Mr. MacDowall between the sums does not appear, therefore, to afford a satisfactory basis for a forecast. GILBERT T. WALKER.

On Fluorescence Absorption.

It is desirable to direct attention to Prof. R. W. Wood's most important paper in the *Philosophical Magazine* for December, 1908, on a method of showing fluorescent absorption directly if it exists; but it seems certain that he has, at the end, drawn a conclusion from his experiments the very opposite, as I venture to think, to that to which they really lead. He compares the light apparently transmitted by a fluorescent body when fluorescence is, and is not, taking place, and finds that there is no difference in the resultant effect. This, I think, is as it should be; but the inference he draws is that there is no difference in the absorption. For my part I must admit that it only confirms my results published in the Philosophical Transactions, vol. cxci., A, 1898, that there is such an absorption; for if there were none such the light *apparently* transmitted would be less when the body is not fluorescing, owing to the fact that the fluorescent light would increase the *apparent* transmission, and a flickering should ensue; but Wood's experiment demonstrates that this is not so. The inference I should draw, then, is that during fluorescence there is an increased absorption of the light transmitted.

Prof. Wood appears to assume, moreover, that the resultant effect on the retina of two successive flashes is equal to the sum of the two acting simultaneously, which is not the case, since the successive flashes act merely as an intermittent single flash would do.

Nichols and Merritt, who have fully confirmed my results spectroscopically, have shown that the absorption effect diminishes as the intensity of the transmitted light increases, so that when the intensity of the transmitted light is large in comparison with that of the fluorescent light there is no effect at all, owing to the fact that this transmitted light itself is sufficiently intense to excite fluorescence, and there is therefore no change of state in the two cases.

If uranium glass is used for the absorption—it was with uranium glass that I observed the effect—the source of the transmitted light should also be uranium glass. I may add that the best results were obtained by using the light from the spark between cadmium electrodes for exciting fluorescence. With a suitable Leyden jar in the circuit, the illumination is sufficiently steady, and any errors in this respect can be detected by the null method I have described. J. BUTLER BURKE.

December 18, 1909.

Adsorption.

"THE above effects, however, become of consequence in those frequent cases in which a muddy liquid is only partially filtered through a dry filter in order that some analytical estimation may be made in a given volume of the filtrate. *The first drops of the filtrate must therefore be discarded.*" The above quotation is from Ostwald's "Foundations of Analytical Chemistry" (English translation), the italics being in the text. Ostwald makes this a purely theoretical deduction, but the practice of discarding first drops does not, I think, originate with him. Doubtless many analysts neglect the precaution, but many use it.

Some experimental work on adsorption which I am at present carrying on seems to point to the practice being quite uncalled for in at least the majority of cases. I am not yet ready to speak definitely, but it seems to be as unnecessary as it would be to reduce weighings to a vacuum standard in everyday analytical work. Ostwald's extreme positiveness, however, makes me wonder whether I have overlooked some serious fault in my experimental methods, and I should be much indebted to anyone who would point out to me any references in the literature which give an *experimental* justification of the practice. The absence of any library facilities in this place makes a systematic search of the literature impossible to me.

The Terminal Velocity of Fall of Small Spheres in Air.

At the Winnipeg meeting of the British Association Prof. Zeleny and Mr. McKeehan read a paper on the terminal velocities which they had found when Lycopodium and other small spores fall through air. The measured terminal velocities were only about half those calculated by Stokes's formula. The fall was steady, no Brownian motion or rotation being visible. The authors of the paper have since succeeded (see NATURE, December 9, 1909, p. 158) in making minute spheres of wax and mercury which do obey the theoretical law, but add that the reason for the deviations in the former cases is not clear.

May not the reason for these deviations be the roughness of the spore? The drops, through surface tension, are smooth and practically perfect spheres, whereas a spore of Lycopodium is very rough relative to its size. (Using a microscope objective with large aperture, and oblique illumination, Lycopodium spores of about 14 μ radius were seen to be coated with hair-like projections.) The spore would, from its roughness, leave a tail of small eddies behind it. The increased energy of this turbulence represents the increased resistance which the spore experiences on account of its roughness, as compared with that experienced by the smooth drop considered in the theoretical law, much as the speed of a ship is lessened when its bottom is foul.

As a suggested experimental test, an increase in the pressure of the air will not affect the viscosity, but will alter the energy in this tail of small eddies. So also would a moderate decrease in the pressure, while yet it would probably not bring the relative size of the spore and of the gaseous molecular free path too close for the theory to be applicable. Should this be the case, however, it would be shown by the appearance of Brownian motion. EDITH A. STONEY.

Positions of Birds' Nests in Hedges.

LIEUT.-COLONEL TULL WALSH's observations as to the positions of nests (NATURE, December 16) are interesting, as they tally with the aspect of arboreal cryptogams, as already noted by me. South-west winds depositing sulphurous and nitrous products to leeward of towns cause lichens and mosses to flourish best on the eastern side of trees and hedges; and, moreover, this is general, for winds bearing spores from the south-west continually play on the trunks and blow away spores as they settle. If it were not for a kind of capillary attraction or rotary motion drawing the spores round the trunk to leeward, or east or north-east, they would never germinate. So the eastern side is the most productive, though often the western aspect may exhibit a greater abundance of species, though less well developed, from the continuous play of spores—and rain—upon the trunk.

Of north and south positions the same may be said, *i.e.* the south is sheltered from fierce, cold north winds, yet open to warm, rain-depositing winds. Again, once established, cryptogams flourish on the southern aspect best owing to its sunny character. North winds blow when spores are not so abundant, and the same applies to boisterous east winds, though these are short-lived.

Apart from wind dispersal of spores, vegetative reproduction tends to favour the same situations, south or east, for south-west winds bring moisture, and, when not laden with poisonous substances, are beneficial; but long-continued wind tends to drive plants to the east side, and absence of sun from north to south.

The causes inducing birds to nest preferably on the eastern and southern sides of hedges (and trees, to some extent) are much the same, *i.e.* protection from wind and the greater safety of a leeward position and amount of sunlight; but in their case, also, there is light dispersal. There is a shadow on the leeward side of hedges for a great part of the day after the early dawn, and this enables birds safely to go in and out without being observed.

The western side presents fewer convenient nesting sites, the branches of hedges being generally bent over from west to east, as seen best on the west coast, affording a better arbour on the east. The south and east face early dawn longest, and this is the favourite season of the birds. At any rate, their song is richest between 4 and 8 a.m. The north and west are open to bright sun but during the *colder* part of the day.

As to the actual distribution of nests, the same positions noticed by Lieut.-Colonel Tull Walsh are favoured by birds in Leicestershire, Shropshire, Surrey, amongst other counties, and seem to be more or less general. The need for studying cryptogamic distribution in relation to wind in connection with the extinction of plants led me to formulate the conclusions noted. It is interesting to observe that they are directly analogous to the position of birds' nests in hedges. Hence the parallel drawn.

Leicester Corporation Museum, December 22.

Studies in Polychæt Larvæ.

MAY I make use of your columns to correct an error in my "Studies in Polychæt Larvæ" in a recent number of the *Q.J.M.S.*? The specimen there described as a young Odontosyllis sp. I have since found to be in reality a fully grown Exogone. I have been unable to identify it with any known species, but as dorsal natatory setæ are quite well known in specimens of Exogone of this size, the conclusions drawn from this specimen are of no value.

With regard to the last section of the same paper, it has lately come to my notice that de Saint-Joseph has shown Claparède and Mecznicow's so-called Spionid larva, in which there are no provisional setæ, to be the larva of the aberrant worm Saccocirrus, and not of one of the Spionidæ. There is, then, no known exception to the rule that free-swimming Spionid larvæ bear provisional setæ.

F. H. GRAVELY.

5 Silver Street, Wellingborough, December 27, 1909.

Cross-fertilisation of Sweet-peas.

I HAVE recently seen two further reiterations of the statement that the sweet-pea is invariably self-fertilised, a statement which I think is often based on an opinion of Charles Darwin's. It may therefore be worth while placing on record an observation made by me in 1907, when examining daily and closely a large quantity of sweet-peas. While *Apis mellifica* failed entirely to open the flower, it was done perpetually by *Megachile willughbiella*, and there was not the least doubt about the cross-fertilisation being effectively brought about by this bee. The point has probably been noted before, but it is worth recording once more in view of the repetition of statements as to the self-fertilisation of sweet-peas.

π.

A Supposed New Mineral.

WHEN we wrote recently (NATURE, October 28, 1909) about a supposed new mineral from Co. Antrim, we were led to believe that the specimen we had received was from the basalt—our information, in fact, was that "a very big pocket of it" had been found in that rock, but the exact locality could not be ascertained at that time, the finder having left home.

We now hear that this gentleman cannot remember where he got the specimen. It certainly cannot be traced to the basalt, and as its composition is unlike that of any known mineral, it seems highly probable that the substance is an artificial product.

THE HEART OF ANTARCTICA.[1]

IMMEDIATELY after the arrival of the British Antarctic Expedition of 1907–9 in New Zealand the attempt was made in NATURE (April 1, 1909, vol. lxxx., p. 130) to estimate its scientific results from the information received by cable. The full details now supplied show that the estimate then made in no way exaggerated the greatness of its achievements. The full story of the expedition, told in these most interesting and beautifully illustrated volumes, shows that its great success was due to careful and scientific foresight in equipment, to the determined and uttermost use of the equipment and staff, and to daring in the field, carried sometimes to the verge of recklessness, but saved from accidents by sound judgment and cool courage.

The main purpose of the expedition was to reach the South Pole, and as that object required an advance into the heart of Antarctica, no better route could have been selected. There can be little doubt that the expedition would have been completely successful and reached the Pole but for the accidents to the ponies. Four of them died in the winter quarters, one from eating some poisoned shavings, and three from eating sand—perhaps due to the craving of horses for salt, that may not have been adequately allowed for in their food. The most irreparable accident was the loss of the last pony during the southern sledge journey by its fall into a crevasse on the Beardmore Glacier. The sledge party was thus deprived of an important part of its reserve food, and the accident was especially annoying, as the pony was to have been killed that night. The horse meat was not a complete success, as it brought on dysentery. Sir Ernest Shackleton explains this somewhat unexpected result by the meat being poisoned by a toxin of exhaustion. As the symptoms of fatigue can be transmitted by inoculation from a tired to an untired dog, the suggestion sounds probable.

The work is prefaced by an admirable introduction by Dr. Mill on previous Antarctic work. The first volume describes the equipment, the vain attempt to land on the eastern side of the Great Ice Barrier, the establishment of headquarters on MacMurdo Sound, and the winter's work there. The motor car proved of great service around the station, but though it ran well on smooth sea ice, it would have been of no use on the soft surface of the Barrier.

The great sledge journey to the south was, therefore, dependent upon the ponies; and these did their work well. The sledging party consisted of Sir Ernest Shackleton, Adams, Wild, and Marshall, with four sledges, each hauled by a pony. The explorers made a quick journey southward until the mountain wall which forms the western boundary of the Ross Sea and of the Great Ice Barrier curved eastward and lay across the route to the Pole. The mountain scarp is breached by a valley occupied by the Beardmore Glacier, which offered a difficult route to the plateau, and up it the explorers forced their way. After many narrow escapes from crevasses, the expedition attained the plateau and marched southward across it until the exhaustion of their food compelled them to turn back at a point only ninety-three miles from the South Pole. No scientific advantage would have been gained by traversing the remaining distance, and, considering the small reserve supply of food, the risks that had been accepted were, if anything, unduly high.

---

[1] "The Heart of the Antarctic. Being the Story of the British Antarctic Expedition, 1907–9." By Sir E. H. Shackleton, C.V.O. With an Introduction by Dr. Hugh Robert Mill. Vol. i., pp. xlviii+372; 132 plates. Vol. ii., pp. xvi+419; 141 plates, 3 maps. (London: W. Heinemann, 1909.) Price, 2 vols., 36*s.* net.

This magnificent sledge journey has practically demonstrated that the South Pole is on a high plateau, which is bounded to the north by a continuation of the mountain scarp of South Victoria Land, and that this scarp trends eastward towards Graham Land.

The second important achievement by the expedition was the daring sledge journey by Prof. David and Messrs. Mawson and Mackay to the South Magnetic Pole. This great feat was all the more remarkable as not one of the three members had any previous Arctic or Antarctic experience. Prof. David's party had to haul its own sledges, make double journeys over most of the way, and work on half rations almost from the first day. They successfully sledged along the coast of Victoria Land, and then up the Larsen Glacier and over the inland ice to the South Magnetic Pole. They ran great risks from crevasses, and had to incur the added danger of not being found by the *Nimrod* on their return to the coast. Had they been delayed a few days they must have missed the ship, and their only chance would then have been to wait until the sea again froze over and they could sledge back to winter quarters.

The scientific results of the expedition are unquestionably of the highest importance. It found that, as was suggested in NATURE in 1901, the mountains of South Victoria Land curve eastward, so that the South Pole stands on a high plateau, of which the scarp facing the Pacific trends towards Graham Land. The structure of the mountains of Graham Land and of South Victoria Land is very different; hence we must expect either a continuation of the fold line of Graham Land between the great scarp of Antarctica and the South Pacific coast, or else that the eastward extension of the fold line of Graham Land has foundered beneath the sea, leaving the coast of Antarctica along the South Pacific of the secondary Pacific type.

The scientific problems raised in the second volume are of wide interest; though only preliminary statements are given, they show the wide range and high quality of the work. The accounts are most definite in regard to geology and biology, and they include appendices on the meteorology, magnetic observations, aurora australis, and on tides and currents. The expedition was fortunate in having such an expert geological staff as Prof. David, of Sydney, Mr. Priestley, of Bristol, and Mr. Mawson, of Adelaide, of whom the last acted also as the physicist to the expedition. The biologist, Mr. James Murray, is a well-known specialist on the smaller animals most likely to live on an Antarctic land. Among the most remarkable of the geological results was Sir E. Shackleton's discovery of several seams of coal and coaly material, and of a band of limestone in the southern continuation of the Beacon Sandstones. He was fortunate in collecting the only recognisable fossil (other than radiolaria) hitherto found in this quadrant of Antarctica; it has been determined by Mr. E. J. Goddard, of Sydney, as a piece of coniferous wood of Upper Devonian or Carboniferous age; it furnishes the only direct evidence of the age of the sandstones that are so important in the geology of South Victoria Land.

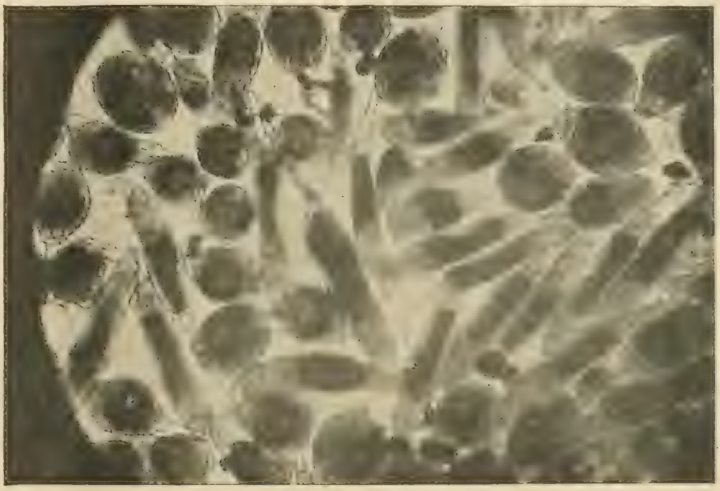

FIG. 1.—The Gregarious Rotifer, which forms blood-red patches in the lakes at Cape Royds. From "The Heart of the Antarctic."

Mr. Priestley's excursion to the mainland opposite the winter quarters also yielded interesting results, which greatly reduce the thickness previously assigned to the Beacon Sandstone, and throw doubt on its invasion by a younger granite. Prof. David determined the geological history of Mount Erebus, as well as obtained most valuable results as to the structure of South Victoria Land.

One of the most instructive of the geological results is Prof. David's description of the Nordenskjöld and Drygalski Glaciers, which continue out to sea as great ice capes for sixteen and thirty miles from the coast. These projections appear to be certainly floating, and, though fully exposed to the gales of this stormy sea, they have not been broken up into icebergs; moreover, solution by sea water appears to be very slow, as Prof. David describes the floating end of the Nordenskjöld Glacier as dwindling away from the failure of fresh supplies of ice from the snow-fields by which it was formerly fed. The Great Ice Barrier appears to be of quite a different origin. Shackleton records in his diary (vol. i., p. 293) that "The Barrier surface is still as level as a billiard table, with no sign of any undulation or rise." And with his keen geographical insight Shackleton discriminated (*e.g.* p. 305) between the Barrier ice and the glacier ice, which in places is thrust into it from the land.

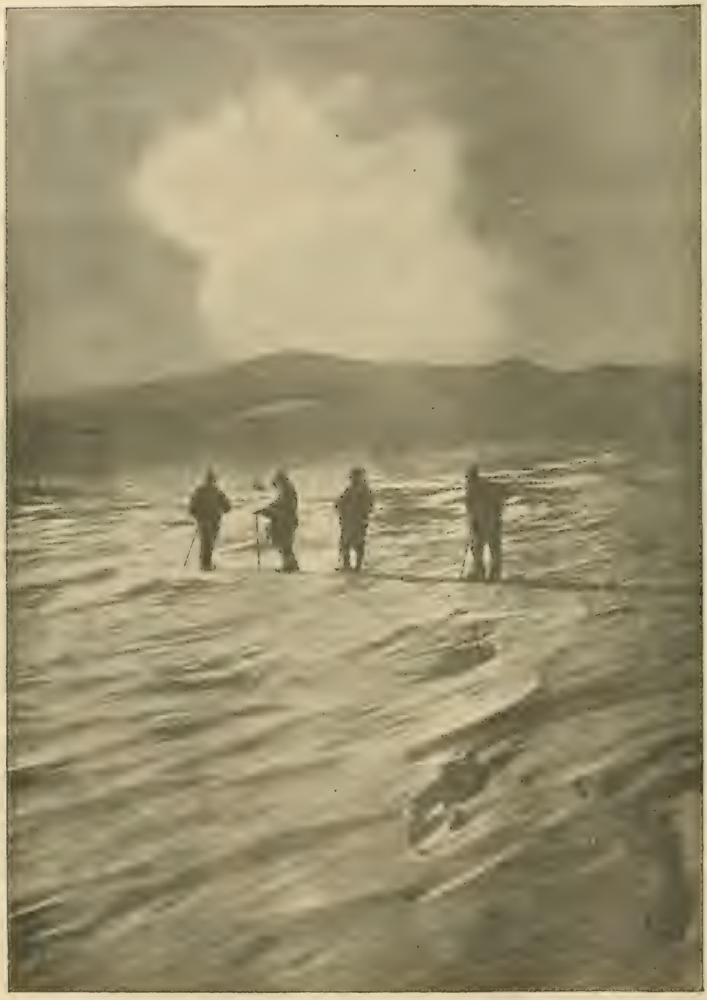

FIG. 2.—One thousand feet below the active cone of Erebus. From "The Heart of the Antarctic."

It would be difficult to explain the striking uniformity in level of the Barrier if it were land ice flowing northward, the conclusion adopted by the staff of the *Discovery* expedition. This view was rejected in NATURE in the reviews, both of Captain Scott's narrative and of the volume on the geological results of the *Discovery* expedition, in favour of the origin of the ice "by the accumulation of layers of snow upon the surface more quickly than the ice was dissolved by the sea beneath" (NATURE, 1906, vol. lxxiii., p. 300). This explanation was then attended by the difficulty that the snowfall was said to be too low. The evidence, however, of the photographs brought back by the *Discovery* seemed so convincing that the writer concluded that the snowfall would be found much larger than was reported. The new observations show that the snowfall at the winter quarters was equivalent to a rainfall of 9½ inches a year, and that on the Barrier the average for the past four years has been 7½ inches. This amount of snow seems adequate for the formation of the Barrier ice from snowfall, and this explanation of its origin is now fully confirmed by Prof. David.

The meteorological results are still indefinite, but further light on the hypothetical South Polar anticyclone may be expected from the full records. The narrative shows that there was a less constant blizzard from the south in the southernmost district than was inferred from the cable report. There was a north wind, for example, behind the party during its ascent of the Beardmore Glacier. Nevertheless, the direction of the ice ridges on the polar plateau shows that its prevalent wind is from the south. The evidence available suggests that, if the South Polar anticyclone exist, it is either less extensive than was thought, or its centre is in the area between the South Pole and the southern Atlantic.

The appendix on the zoological results gives many interesting particulars as to the habits of the penguins and seals. Mr. Murray is an expert on the rotifers and tardigrades, of which he found a rich fauna in lakelets near the winter quarters. They are only thawed occasionally in the summer, and live in ice through most of the year. They were subjected to various experiments to test their resistance to low temperatures and ultra-saline waters, and they triumphantly survived. Mr. Murray discusses the geographical relations of this fauna, and concludes from the poverty in species, and their wide distribution, that it is due to modern immigration. Mr. Murray collected many marine animals from what he describes as the living carpet covering the sea-floor in McMurdo Sound.

The lakes also contain a rich growth of fungus, which Prof. David describes as giving rise to beds of peat. It is therefore possible that coaly material may be formed in the Antarctic area even under existing conditions. The fossil conifer found by Shackleton shows that Antarctica once had a milder climate than at present, a fact already established by the work of Swedish expeditions, and only natural as a correlative of the warmer conditions that once prevailed in Greenland and Spitsbergen.

J. W. Gregory.

GAME PRESERVES IN BRITISH EAST AFRICA.[1]

Colonel Patterson is already well known to the British reading public by his remarkably interesting book on his destruction of the man-eating lions which infested the eastern section of the Uganda Railway during its construction and first years of activity. He returned to East Africa in 1907, but whether as a Government servant or as a private traveller is not clearly stated in the book under review (which it may at once be said is exceedingly interesting to a wide circle of readers—those who love thrilling adventures, those whose chief interest is in sport, and to students of the East African mammalia). Whether he was all the time or not on Government business, he had not been long back in East Africa before he was requested to undertake an important mission to the little-known north of the Protectorate across the Guaso Nyiro, there to report on the most suitable frontier to be fixed as the eastern limit of the great Northern Game Reserve.

Seeing the risky and important nature of this journey, the need to avoid any unnecessary responsibility and cause for anxiety, and, if need be, to travel light and with swiftness, it was (as the author half admits) unwise to have allowed two friends (an English sportsman and his wife) to accompany him into such a remote and possibly dangerous part. However, they went; the friend was killed by a revolver accident, and the author of the book was faced with the dilemma as to whether he should immediately escort the widow back to civilisation, some three hundred miles away, or complete his survey (another fifty miles) and then return. He very sensibly adopted the last course. It should be mentioned that the lady with whom circumstances obliged him to travel showed herself a brave woman and an excellent rifle shot. She faced elephants, lions, rhinoceroses and buffalo, sickness of herself and others, mutinous followers, with equal courage and coolness. But it is, of course, a commonplace by now to point out that in the hardships of exploration and the dangers of big-game shooting, British women, some Americans, and a few French and German women, are quite on a par with the men of their race.

One can admire their pluck, but at the same time regret that it should be thrown away on often unnecessary dangers in attacking wild animals far too interesting to be killed. But apparently the men and women of the Caucasian subspecies will not rest content until every big beast and every bird of remarkable plumage is exterminated.

Colonel Patterson does not tell us (so far as we can gather) what recommendation he made as to the definition of the eastern boundaries of this Northern Game Reserve; he hints, however, in one place, that its area is unwieldy (which is quite true), and that as it stands it is far too large to be properly supervised. The whole question, it is to be feared, is purely academic in the British Empire. Large or small as the game reserve may be, the native peasant or the nomad hunter *takes* leave, the Royal or distinguished visitor is *granted* leave, and somehow the shooting goes on. Abyssinians, Somalis, Arabs, and even Goanese traders, adventurers, or bandits, enter this Northern Game Reserve and defy the law to stop them or punish them, and it is said the Boer settlers of the western part of the Protectorate are doing the same.

Fig. 1.—Camels crossing the Kaisoot Desert. From "In the Grip of the Nyika."

The history of the East Africa Protectorate will, no doubt, be very like the history of Cape Colony and the Orange State: the big game will be nearly all killed out, not within the next ten, but certainly within the next fifty years. For it occupies land which in many parts is really well adapted for human occupation (with all the appliances we now possess for turning the tropics to account). The only way to preserve the game to a reasonable degree in selected parts of Africa will be to convince ourselves that these "useless" beasts *are* worth preserving for their beauty or their interest; secondly, to impress that principle in their childhood's education on the rising generation of the white race; and, thirdly, to spend time and money to impart this doctrine to the natives of Africa, making it well worth their while to cooperate with us.

---

[1] "In the Grip of the Nyika: Further Adventures in British East Africa." By Lieut.-Col. J. H. Patterson, D.S.O. Pp. xv+389. (London: Macmillan and Co., Ltd., 1909.) Price 7s. 6d. net.

Of course the Northern Game Reserve is far too large. Colonel Patterson alludes to its history. It was jointly instituted by two commissioners of East Africa and Uganda—Sir Arthur Hardinge and the writer of this review—as a temporary means of arresting the devastations of Europeans, Somalis, Goanese, &c., until the question of game preservation could be more deliberately dealt with in legislation. The time has now come (since the entire reserve of 38,000 miles lies within the limits of the East Africa Protectorate) to cut up this area into (say) three "national parks" of, perhaps, five thousand square miles each, and provide each park with a sufficient staff of game wardens. The remainder of the country would then be allotted to the expansion of native tribes, or be prudently held in reserve for future foreign settlement, if at present without human inhabitants. Disappointing as this reduction might seem, it would be better for the preservation of rare animals to set aside three or four areas each about the size of Yorkshire, in which *no one*, millionaire or prince, soldier or civilian, was to be allowed to shoot, than to mark on the map a reserve as large as Scotland, Wales, and the Isle of Man put together, and to be quite unable to control within its limits either natives or Europeans.

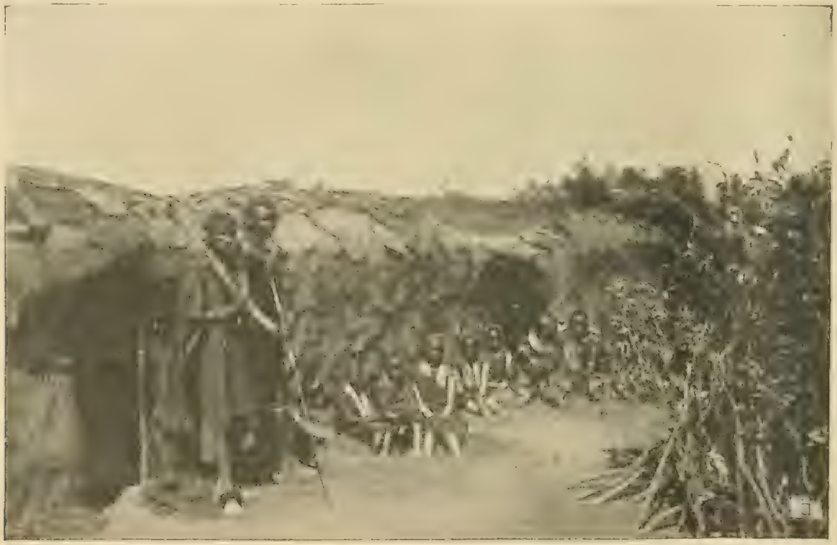

FIG. 2.—A Masai Manyatta. From "In the Grip of the Nyika."

These reserves might be specially selected for the preservation of the more important beasts; thus one could be marked out where rhinoceroses were most abundant; another to save and multiply the handsome Beisa oryx; a third for elephants, and a fourth for the giraffe; and the game wardens must be *civilians* and *biologists*, men of the stamp of the Indian forestry officers.

Colonel Patterson's book reveals the existence of very fine specimens of eland in British East Africa, on which the Government of that Protectorate should keep an eye. It gives new information about the course of the still mysterious Guaso Nyiro river, and contains interesting particulars concerning the Samburu negroids in the northern part of British East Africa. It suggests, indirectly, how much of interest to the student of Africa awaits discovery and explanation in the semi-desert regions that stretch between the Guaso Nyiro and the middle Juba.

H. H. JOHNSTON.

PROBLEMS OF SCIENCE TEACHING IN SCHOOLS.[1]

A DEFECT of intellectual character, national in its incidence, is revealed at conferences of teachers and in the reports issued by associations of schoolmasters and others concerned in educating English boys and girls. In this country the teacher, like the man in the street, is too narrowly "practical"; he regards the discussion of fundamental principles as unprofitable. Thus it is that we find details concerning exposition (*e.g.* of calorimetry) receiving the careful attention of the physics teachers of our leading schools before anyone has sought to answer the question, "Why teach physics?"

We admit that there is some virtue in the insularity of mind which produces this illogical treatment of class-room problems. The schoolmaster says that the aim of teaching chemistry is *to teach chemistry*, and concentrates his attention upon making each lesson effective, with the result that boys are made to do some definite work. Yet it can hardly be denied that neglect of the wider questions infallibly narrows the teacher's outlook, and that this narrowing sooner or later eliminates from his teaching all the vitalising enthusiasm for knowledge which a man who *believes* in his teaching can inspire in his boys. The best results are obtainable only when the teacher and the boys believe that the work which the class is doing is really worth while. How can a teacher hold such a belief steadfastly through the disillusions of experience unless he has thought out, to some extent, the why and whereunto of his work?

---

[1] The American Federation of Teachers of the Mathematical and the Natural Sciences. Bulletin No. 2, November, 1909. (Secretary, C. R. Mann, University of Chicago.)

Another objection to the scrappy manner of approaching problems of class-room and laboratory is that such procedure is unscientific because unorganised. An analysis of the recommendations which have been published by societies of teachers in England will be fairly certain to reveal example after example of statements which you can neither accept nor deny until you have settled the *aim* which justifies inclusion of science in the curriculum. Nor is it to be imagined that a realisation of the educational functions of the various subjects is of import only to persons placed in authority—to the high priests of our educational hierarchy. Such a realisation (or the absence of it) affects every minute of every lesson given by the humblest practitioner of the teacher's craft. In all teaching, the objective dictates the method.

Granted that the fundamental problem of science teaching is the determination of the aim of such teaching, how far is it possible to generalise? How far will the aim depend upon the sex, range of age, previous preparation, and probable after-life of the majority of the pupils? It is easy to enunciate a few general truths, but it is clear that each school has its own special problem. Every subject worthy of a place in the school course does at least two things—(1) it enriches the mental content with valuable knowledge; (2) it develops mental power through the process of acquiring the knowledge. The former is too often under-rated by the schoolmaster, the latter by his lay critic, *e.g.* the business man. We must promote the fitness of the boy for his particular *rôle* in life, and at the same time give him as intelligent an understanding as possible of his fellow-men and their work. The boy should acquire some sense of his inheritance in the round world and all that therein is. Properly taught, science will have a humanistic value; the teachers of literary subjects must be made to feel, by the demonstrated effect of the science teaching in evolving many-sided interest in the boy, that they have not the sole title to "the humanities." But beyond such broad generalities there are no rules to be laid down, and the individual teacher must study his own case. In this task he might derive much assistance from debate with colleagues and in educational conferences.

Teachers in the United States have organised large federations of associations in order to discuss the broad problems of teaching. The concluding paper of a "Symposium on the Purpose and Organisation of Physics Teaching in Secondary Schools" appeared last March, and now we find in "Bulletin Number Two" papers on "The Problems of Science Teaching," written by President Ira Remsen (chemistry), Messrs. G. F. Stradling (physics), J. M. Coulter (botany), W. T. Campbell (mathematics), and N. M. Fenneman (physical geography). We abstract from the paper which deals with botanical instruction. The first problem, writes Prof. Coulter, is the prepared teacher, a problem not peculiar to botany, but peculiarly conspicuous. The prepared teacher means one who, in addition to good laboratory and field experience, has a clear conception of the purpose of botany in secondary schools, as distinct from its purpose in higher institutions. To inject into these schools miniature duplicates of college and university courses is to defeat their purpose. There is no ideal method of first attack; the most natural one is the one nearest to the pupils. It would be very unfortunate for any committee to assume to determine that some one method of approach is the best. A current problem is the place of the economic aspects of botany. The older educational theory emphasised mental discipline to the exclusion of useful things, so that sometimes no useful plants were included in the course. In these days there is a tendency to the other extreme, and it is proposed to substitute agriculture for botany—a short-sighted change, because the most practical thing in the world is the foundation of pure science upon which applied science rests. The fundamentals of botany can be obtained from useful plants; but there should never be a straining after such plants at the expense of a clear illustration of the principle to be established. Referring to the proposal to include botany in general biology, using plants and animals indiscriminately for giving knowledge of biological principles, the author finds that this method is inappropriate to immature students, as the perspective is far too large to be grasped by their limited experience; but he suggests that the question be settled in conference. Finally, Prof. Coulter asks for a clear statement of the real value of botany from the point of view of the pupil—a serious attempt to answer the honest question, "What is it good for?"

Our only comment is that the "prepared teacher" who has answered the last question for his own school is in a fair way to solve the other problems propounded. We welcome this series of papers, for unless the teachers of science study their work with scientific method, *quis custodiet?*

G. F. DANIELL.

MAGNETIC SURVEY OF SOUTH AFRICA.[1]

THE Cambridge University Press has published for the Royal Society a work giving an account of the results of the magnetic survey of South Africa carried out by Prof. Beattie, of Cape Town, with the aid of grants from the Royal Society, the British Association, and the Governments of the Crown Colonies in South Africa. The author, in the preface, acknowledges help from a number of scientific gentlemen in South Africa, and he has been fortunate in securing for the final presentation of the work the help and acute judgment of Dr. Charles Chree. The observations were made at some 400 stations in British South Africa, and extend over the period from 1898 to 1906, and the region is bounded roughly by latitudes 18° to 34° S., and by longitudes 20° to 36° E. The epoch to which the results have been reduced is July 1, 1903.

The amount of observational work required is very great and of a peculiarly monotonous type. The reduction of the results must have been a still more arduous task. It is difficult for anyone looking at the final results to realise the amount of sheer labour involved.

A work of this kind appeals in the main to professional magneticians, and for this reason the first part of chapter i. strikes us as a little out of place. It was hardly necessary to define the magnetic elements, but if the author thought it well to do so, he might have made them strictly scientific, instead of giving the kind of descriptive definitions which are suitable for a popular lecture. Similarly, a very "rough" method of finding declination is given. It looks trifling in a work of professional character.

Not the least difficulty in making a magnetic survey is the fact that the magnetic elements are constantly changing. The only satisfactory way of eliminating this trouble is by reference to a recording magnetic station within reasonable distance of the point at which the absolute observations are taken. Unfortunately, there is no such station in South Africa, and thus Prof. Beattie has been severely at a disadvantage. He has attempted by other means to eliminate the effects of periodic and secular change, but after giving an account of his attempts he concludes that the result is somewhat illusory, and probably most impartial readers will agree with him. This naturally sets a limit to the general accuracy, and unfortunately it is a case in which the excellent maxim of considering the pennies does not ensure that the pounds will behave with their reputed propriety.

---

[1] Report of a Magnetic Survey of South Africa. By Prof. J. C. Beattie. Pp. x+235. (Cambridge: University Press, 1909.) Price 21*s.* net.

A statement of the reduced results and tables for the purpose of drawing charts of equal values of any element naturally occupies a considerable proportion of the book.

The problem of drawing equivalent curves from observations at discrete points calls for great experience and discrimination on the part of the operator. As regards the main features, no question can arise. The results agree well with the known geological formation, of which an excellent map is given. Moreover, the localisation of magnetic districts is fairly definite and must prove of value to geological and mining science; but some of the minor fluctuations may as well be due to local magnetic matter as to incidental error, from which, under the conditions, the observations cannot be quite free. The manner of presentation of the results will, we feel sure, meet with general approval. We trust that the author will not accuse us of unduly exceeding the limits of reasonable criticism if we suggest that the phrasing "with one instrument first, then with the other, and finally with the one again," is not the most elegant way of describing the operation of comparing instruments. Further, X, Y, Z, T so naturally represent the northerly, westerly, vertical components and total force that we deprecate the use of Z for total force and T for the northerly component.

In appendices which really occupy more than half the volume, a statement of the method of reduction and of the station observations is given. That the observations should occupy so large a space is only right, for we trust that future generations will desire to examine the record of this important work. In Appendix D the author gives a typical example of reduction of the determinations of horizontal force. We observe that Prof. Beattie estimates times in the vibration experiment to one-twentieth of a second. While several magneticians adopt this practice, we have some doubt whether, by counting chronometer ticks, one can always be certain of one-tenth of a second. Even with an electric chronograph it is not customary to estimate a single transit to nearer than one-tenth of a second.

In the determination of horizontal force a number of points arise. One's object being the value at a definite instant, we require a vibration and deflection experiment. In taking a vibration experiment, both before and after the deflection experiment, Prof. Beattie is well advised, but we are unable to follow the logic of his elaborate system of taking means. If the change in horizontal force during the experiments is linear and small, it will not make the least difference whether we take the average of the first and second vibration experiments or adopt Prof. Beattie's more elaborate procedure; while if the question enters on squares and non-linear change, we would point out that this has not been examined fully on the theoretical side. Again, we notice that the practice of reversing the magnet at a given distance was followed. A really better average is got by changing the distance on each reversal of the magnet according to the Kew practice. Whatever the elaborate way of combining the results may mean, it does not eliminate the frequent possibility of the value of H during the deflection experiment being different from the average value during the two vibration experiments, nor the fact that H may differ for the 30-cm. and the 40-cm. distances in the deflection experiment. These are, however, criticisms of detail, and do not affect the general accuracy of the final result, and the record of the first South African survey will remain a memorial to the industry and conscientious work of its director.

G. W. W.

M. BOUQUET DE LA GRYE.

AMONG French men of science, few have been more respected or have worked more indefatigably than M. Bouquet de la Grye, whose death, at the advanced age of eighty-two, was recently announced. His official work was more immediately connected with engineering and hydrography, but his scientific interests were wide, and he was equally well known as an astronomer and geodesist. As marking his qualities as a hydrographer, it is sufficient to recall that at an early age, shortly after leaving the École Polytechnique, he took a prominent part in charting the parts of the Mediterranean adjacent to the coasts of Italy and the Island of Elba. To estimate correctly the importance of this work, we must remember that in the early 'fifties, methods of surveying were not so systematised as they have since become, and mechanical routine had not displaced opportunities for original treatment. Subsequently, he was engaged in correcting the charts of the French Atlantic coast, and in the course of this work he assisted in improving the navigation of the River Loire and contributed greatly to the establishment of the successful port of Nantes. His work on river navigation, and his appreciation of the facilities for traffic which inland waterways offered, seem to have inspired him with the hope of converting Paris into a seaport, utilising the Seine, which he proposed to deepen for the purpose, and avoiding its irregular bends by the construction of canals. A system of docks and the whole machinery of a seaport were to be constructed at Saint Denis. Needless to say that this project, which demonstrates the extent of the imagination and enterprise of the regretted man of science, has not met with public favour. It seems to be the fate of canals either to be rendered useless by the increasing growth in the tonnage of steamers, or to involve such gigantic expenditure in construction that their commercial success is jeopardised at the outset.

In his astronomical work, M. Bouquet de la Grye will be remembered in connection with his loyal and long continued efforts to render the observations of the transit of Venus available for the determination of the solar parallax. In 1874, and again in 1882, he took active part in the preparations and in the actual observations, on the first occasion visiting Campbell Island, and on the second, Mexico. This method of determining the sun's distance may now be discredited. Improved technique and greater knowledge have permitted the use of methods of greater accuracy, providing results less difficult of interpretation; but it would be ungenerous to undervalue the devotion of astronomers of a past generation, who have been actuated by a sincere desire to benefit science and have exhibited both ingenuity and energy in the pursuit. It would be scarcely too much to say that for the last thirty years this subject occupied the attention of the deceased astronomer. The care and elaboration M. de la Grye bestowed on the reduction of the observations, sometimes devising ingenious experiments to remove photographic difficulties, at others undertaking new determinations of longitude in order to improve the data, are beyond all praise.

M. de la Grye's attention to geodesy supplied him with another outlet to his energy, and perhaps a relaxation. As a member of the Bureau des Longitudes, he interested himself in all questions which involved the figure of the earth, tidal movements, the variation of gravity or of latitude. He was a regular attendant at all geodetic congresses, reporting their proceedings and upholding their objects. The proposed scheme for the re-measurement of an arc of meridian in Peru had his hearty support. In the details he took the greatest interest, and his suggestions were appreciated by the commission. The encouraging support he was ever ready to extend to others, and his long experience, always at the command of those who sought his counsel, will be long missed by his colleagues, who well know how irreparable is their loss.

PROF. J. S. H. PELLAT.

It is with deep regret that we see the announcement of the death, after a very short illness, of M. Pellat, professor of physics at the Sorbonne (Paris). Joseph Solange Henry Pellat was born at Grenoble on July 27, 1850, and he died on the December 18 last. After leaving the École normale supérieure, he started work as meteorologist in the Paris Observatory. His stay there was not long, however, for he was soon appointed as professor in the Collège Rollin, and then at the Lycée Louis-le-Grand. In 1885 he was appointed a lecturer in the faculty of science at the Sorbonne, and was ultimately given a chair, which was created specially for him. He occupied many distinguished positions. He was for many years general secretary of the French Physical Society, and also occupied the presidential chair. He was vice-president in 1896 of the Société des Électriciens, and was president of the same society at the time of his death.

Prof. Pellat was one of a brilliant group of pupils of Prof. Jamin, whose laboratory at the Seine was a focus for physical studies. His scientific work covers nearly the whole range of physics. Of practical importance we may single out his construction of an electrodynamometer, in which the force is measured by which one coil is pulled inside another when a current flows through each. Measurements of the electrochemical equivalent of silver and experiments on the cadmium cell fall within the same category. It was, however, for questions having a theoretical bearing that he had the greatest interest. Some of his early work consisted in measuring the differences of potential of contact between two metals; and throughout his life, in common with practically all French physicists, he adhered to the views then held as to the existence and origin of these potential-differences. In a paper in the *Journal de Physique* for March, 1908, he combated the theory of Nernst in regard to the performance of a voltaic cell, and considered that his experiments proved that a metal immersed in a solution of one of its salts is sensibly at the same potential as the latter, at any rate when the solution is not too dilute.

Prof. Pellat was greatly interested in the properties of dielectrics; he constructed apparatus for measuring dielectric constants, and also (in 1899) for measuring their rate of change with temperature. The latter data were required to illustrate the application of a theorem deduced by him thermodynamically, according to which the increase of the energy of a condenser on being charged is only partly represented in general by the electrical energy, an intake (positive or negative) of heat occurring at the same time whenever the dielectric constant varies with temperature. In 1895 he promulgated a new method of dealing with electrostatic phenomena in the general case of heterogeneous dielectrics, in which Coulomb's law is dispensed with, and use is made of three experimental principles in conjunction with the two laws of thermodynamics. In an early paper on the influence of a metal on the nature of the surface of another metal placed a small distance away from it, he anticipated one of the modern phenomena of rays by showing that lead emits something capable of affecting a neighbouring photographic plate in the dark.

Of his devotion, zeal, and enthusiasm, M. Bouty speaks in the funeral oration (*Revue scientifique* for January 1), from which we have gleaned many of the above facts. He lived as in a beautiful dream. The taste for experimenting he had contracted as a youth. His experimental ingenuity was never at fault. He had furnished his laboratory with apparatus of his own invention. His lectures swarmed with original experiments. "Pellat had inherited a name rightly celebrated in juridical science. He transmits it to his widow and children shining with an added light."

DUKE KARL THEODORE OF BAVARIA.

The subjoined extract from the official gazette of the Principality of Monaco, referring to the death of Duke Karl Theodore of Bavaria, is worthy of being put on record as an appreciation of one great personage of high rank by another, and an acknowledgment that the nobility of station which commands the greatest respect is that which carries with it personal service to the community.

> Son Altesse Royale Charles-Théodore, Duc en Bavière, qui vient de mourir dans Sa résidence de Bad Kreuth, était le beau-père de Son Altesse le Duc d'Urach et Sa disparition atteint profondément le Prince Albert dans Ses affections les plus chères.
>
> L'alliance entre la Famille des Ducs en Bavière et celle des Princes de Monaco n'avait pas, seule, rapproché les deux Princes; il existait aussi entre Eux une sympathie étroite basée sur la communauté de Leurs goûts pour le travail scientifique et le progrès des idées.
>
> Le Duc Charles-Théodore, après avoir fait de brillantes études médicales, S'était spécialisé dans l'oculistique et pratiqua avec une habileté qui Lui attira une clientèle considérable: non pas celle qui apporte à l'opérateur une fortune, mais celle qui, au contraire, sort de chez lui moins pauvre qu'elle n'y était entrée.
>
> Charles-Théodore fonda des cliniques, et ce Prince qui, dès sa jeunesse, avait senti qu'une couronne royale impose avant tout la pratique du bien, y fit des opérations très nombreuses. Dans cette tâche que Sa haute intelligence se donnait, il était secondé par Sa femme dont le cœur formait le digne pendant du Sien. Et le couple exemplaire vivait ainsi depuis trente-quatre ans sans être séparé un seul jour, si ce n'est quand l'Empereur Guillaume, blessé à l'œil, demanda les soins du Duc. Sa résidence de Kreuth, située au milieu des Alpes Bavaroises, loin des élégances mondaines, devenait vers le mois d'octobre le lieu de réunion d'une nombreuse famille que plusieurs amis, des confrères ou des professeurs, rejoignaient toujours avec joie. Alors se succédaient les chasses au cerf ou au chamois, celles qui se font dans les conditions vigoureuses, séduisantes pour des chasseurs de race: et le Prince Albert y trouvait régulièrement, depuis seize ans, la compensation de Sa vie laborieuse.
>
> Il faut pleurer avec tout son cœur la disparition du

Duc Charles-Théodore, car Son existence était une leçon pour les hommes d'un rang élevé qui se contentent de vivre et de jouir; elle en était une également pour les humbles en leur apprenant de quelle façon il faut comprendre la vraie fraternité. Mais elle enseignait aussi à la jeunesse moderne, si rarement soucieuse de sa propre dignité, comment on traverse la vie dans toute la fière simplicité qui ne veut rien devoir à personne.

Et pour terminer cette existence admirable, le Duc Charles-Théodore, par l'expression formelle d'une dernière volonté, a maintenu jusqu'à l'ensevelissement de Sa dépouille, la simplicité de toute Sa vie: le concours des personnalités impériales et royales déjà accourues à Munich, celui de l'armée auquel Sa qualité royale lui donnait droit, celui des municipalités de la Bavière où sans doute il n'existe pas un village qui ne Lui ait envoyé des malades, celui de six mille opérés qui Lui doivent la vue, toutes les manifestations capables de flatter la vanité humaine furent écartées doucement; et jeudi dernier Son cercueil descendit, en présence de la famille seule, dans le caveau princier.

Cependant jamais funérailles ne furent plus grandioses, car tout un peuple était consterné devant la perte irréparable qu'il venait de faire.

NOTES.

We learn from the *Times* of January 3 that the will of the late Dr. Ludwig Mond directs his trustees, on the death of Mrs. Mond, to set aside two sums of 50,000*l.* each, free of duty, one to be payable to the Royal Society and the other to the University of Heidelberg. The will provides that the income of the 50,000*l.* bequeathed to the Royal Society "is to be employed in the endowment of research in natural science, more particularly, but not exclusively, in chemistry and physics, by providing rewards for new discoveries and pecuniary assistance (including scholarships) to persons pursuing scientific investigations, and in supplying apparatus and appliances for laboratories and observatories, and, so far as consistent with the Mortmain and Charitable Uses Act, 1888, or other similar provisions, in improving existing or in erecting new laboratories and observatories, and in such other manner as the Royal Society shall decide to be best calculated to promote scientific research, and also in providing, so far and in such amounts as the council of the Royal Society shall from time to time determine, for the publication and circulation of the reports and papers communicated to the said society, and for the preparation and publication of catalogues and indexes of scientific literature which the Royal Society may have undertaken or may in future undertake." Similar conditions govern the bequest to the University of Heidelberg. Dr. Mond also left three sums, each of 20,000*l.*, one for the authorities of the Akademie der bildenden Kunste at Munich, to be applied for the promotion of the arts of sculpture and painting; a second for providing pensions or occasional pecuniary assistance to aged or disabled workmen of Messrs. Brunner, Mond and Co., Ltd., or their successors, in the works at Northwich, Sandbach, and elsewhere; the third for the municipal authorities of Cassel.

Sir James Dewar, F.R.S., has been elected a foreign member of the Reale Accademia dei Lincei (Academy of Sciences) of Rome, in the section of physical, mathematical, and natural sciences. The King of Italy has signified his approval of this election.

M. Émile Picard, vice-president of the Paris Academy of Sciences, has been elected president for 1910, and is succeeded by M. Armand Gautier as vice-president.

The death is announced of Mr. W. Earl Hodgson, author of books on "Trout-fishing," "Salmon-fishing," and other works on fishing and popular natural history.

We notice with regret the death, on January 1, of Sir Edward L. Williams, in his eighty-second year. Sir Edward Williams was well known as the designer of the Manchester Ship Canal, which took twelve years to construct. He acted as chief engineer during the work of construction and on the completion of the canal in 1894 was knighted by Queen Victoria.

The annual general meeting of the Institute of Metals will be held at the Institution of Mechanical Engineers, Westminster, on Tuesday and Wednesday, January 18 and 19. The new president of the institute, Sir Gerald Muntz, Bart., will deliver his presidential address on the former day.

It was announced by the president of the Chemical Society at the last meeting that in view of the completion of fifty years' fellowship by the past presidents Sir Henry Roscoe, Sir William Crookes, Dr. Hugo Müller, and Dr. A. Vernon Harcourt, the council has resolved to entertain these fellows as guests of the society at a dinner to be held some time at the end of May or beginning of June.

The following appointments have been made to the Indian Agricultural Service:—imperial agricultural bacteriologist, Mr. C. M. Hutchinson; supernumerary mycologist, Mr. F. J. F. Shaw; supernumerary agriculturist, Mr. G. R. Hilson. The two posts of assistant superintendent recently vacant in the natural history section of the Indian Museum, Calcutta, have been filled by the selection of Mr. Stanley W. Kemp and Mr. F. H. Gravely.

We offer our congratulations to the *Chemical News*, which has just completed the fiftieth year of its existence and its hundredth volume. The Chemists' Club of New York and the American Chemical Society have sent Sir William Crookes messages of congratulation on the jubilee anniversary of his editorship of the journal, and the former institution has elected him an honorary member in recognition of his services to the science of chemistry.

The Geneva correspondent of the *Times* states that the Swiss Federal Government has decided to send a scientific expedition into the unexplored parts of Bolivia under the leadership of Prof. O. Fuhrmann, of the University of Neuchâtel. The explorers will leave Switzerland for South America on July 1, and their object will be to study the fauna, flora, and climate of the country. It is stated that several English and American men of science are to join the expedition at their expense.

On Tuesday, January 18, Prof. W. A. Herdman, F.R.S., will commence a course of three lectures at the Royal Institution on "The Cultivation of the Sea," and on Thursday, January 20, the Rev. C. H. W. Johns will deliver the first of two lectures on "Assyriology." The Friday evening discourse on January 21 will be delivered by Sir James Dewar, F.R.S., on "Light Reactions at Low Temperatures," and on February 4 by Prof. W. Bateson, F.R.S., on "The Heredity of Sex."

The death is announced, in his sixty-eighth year, of Dr. Charles B. Dudley. For a short time after his graduation at Yale he was an assistant in the department of physics at the University of Pennsylvania. Since 1875 he had been the chief chemist to the Pennsylvania Railroad Company, in which capacity he made important investigations relating to the composition of steel rails and of the lubricating oils used on railways. He was president of the American Chemical Society from 1896 to 1898. From 1902 to 1908 he was president of the American Society for

Testing Materials, and was recently elected president of the international society of a similar name.

THROUGH the kindness of Mr. and Mrs. Wickham Boynton, the collection of birds formed by the late Sir Henry Boynton, which for many years has been exhibited in the large room at Burton Agnes Hall, has been placed in the Municipal Museum at Hull. As all ornithologists are aware, Sir Henry's collection of birds, principally obtained by his own gun, was one of unusual interest and importance, and contains many great rarities. There are above 200 cases in all, and besides being valuable by reason of the scarcity of the specimens, the collection is interesting from the fact that in many cases both sexes of birds are represented, and in some instances there are also the young. Each case has been exceedingly well set up, and the whole forms a collection such as is rarely seen together. In addition to this, the Hull Museum has also recently acquired the collection of birds (about seventy cases) formed by Mr. Riley Fortune. This collection consists principally of Yorkshire specimens, and fortunately serves well to fill in the gaps in Sir Henry Boynton's collection. These, together with the Pease collection already in the museum, will enable the authorities at Hull to have a display of birds such as will be difficult to surpass in any northern museum.

THE President of the Local Government Board has appointed Dr. Eastwood, one of the pathologists of the Royal Commission on Tuberculosis, an additional medical inspector of the Board, with the special view of his undertaking pathological investigations. Provision also has been made for the necessary assistance and laboratories. The immediate object will be to apply to public health work the important results obtained by the Royal Commission on Tuberculosis, and thereby to ensure the freedom of important foods from the infection of this disease. It is intended also to investigate the similar problems which are constantly arising in connection with other infectious diseases. These investigations will be concerned chiefly with current doubtful points in regard to disease. The new work thus inaugurated by Mr. Burns will include inquiry as to the pathological methods of diagnosis of disease already utilised in the public health work of many sanitary authorities. It is expected that by interchange of information good work will be encouraged and extended, and that coordination and standardisation of the bacteriological methods of diagnosis of disease will be secured.

THE weekly returns of the Registrar-General show that in 1909, taking the returns for the fifty-two weeks ending with Christmas Day, the total deaths in London were 70,988. This is 3883 fewer deaths than the average for the previous five years, but it is 2353 more than in 1908, which, so far, is the healthiest year on record; the year which has just closed is, however, the second healthiest on record. The deaths in London for the respective quarters were 23,761, 16,917, 13,727, and 16,583; the rates per annum for every 1000 persons living were, for the respective quarters, 19·7, 14·0, 11·4, and 13·8. For the urban districts represented by the seventy-six great towns of England and Wales, the death-rates for the several quarters were 18·8, 14·5, 11·9, and 14·1.

WE have received a copy of a paper by Messrs. H. B. Torrey and F. L. Kleeberger, issued in the zoological series of the University of California Publications, on three new species of the actinarian genus Cerianthus from southern California.

WE have to acknowledge the receipt of a copy of the report of the Clifton College Scientific Society for 1908–9, this being the first printed report issued by that body for the last two-and-twenty years. The resumption of the issue will, it is hoped, enable members to keep more readily in touch with the work of sections other than those in which they are specially interested.

To the first part of *Sitzungsberichte der Niederrhein. Ges. f. Natur- und Heilkunde in Bonn* for 1909, Prof. G. Steinmann contributes an illustrated paper on the problem of ammonite-phylogeny, as exemplified, in this instance, by the genus Heterotissotia. It is concluded that, in place of being a member of the "Circumnodosi" group, Heterotissotia is really related to the Triassic Ceratites, of which it is to be regarded as the Cretaceous descendant. Accordingly, the original view of von Buchs as to the existence of Cretaceous as well as Triassic Ceratites is maintained by the author to be valid.

IN *Prometheus* of December 8, 1909, Drs. P. and E. von Hass, in the course of an article on the origin of the upright posture in man, assert that the ancestors of the human race used their canines for tearing the hide and flesh of the animals on which they fed (how these animals were killed is not explained), but that when they learnt to employ mussel-shells or flint-flakes for this purpose, their tusks, as being no longer necessary, rapidly degenerated. On the other hand, in a recent article in the *Daily Telegraph*, Sir E. R. Lankester has expressly stated that ancestral man never used his tusks for rending flesh. Whom are we to believe?

IN the issue of the *Yorkshire Weekly Post* for December 18, 1909, the natural history correspondent refers again to the killing of birds for the sake of ascertaining whether they have been ringed, quoting as instances a heron shot in Cheshire and a black-headed gull in Lancashire. The heron, he remarks, is protected in Cheshire, as in most other counties, so that the slaughter was illegal as well as unnecessary. In the case of a robin ringed at Glasgow, and picked up dead at the same place a few months later, he asks if there is any use in the ringing of such birds.

FROM the evidence of actual specimens and information obtained by Mr. Rothschild from his agents in California, Mr. Lydekker announces in the *Field* of December 25, 1909, that the so-called Californian elephant-seal to which Gill applied the name *Macrorhinus angustirostris* appears to be identical with *M. leoninus*, as typified by the specimens obtained by Lord Anson on Juan Fernandez, and named by Linnæus. The seals formerly inhabiting Guadalupe Island and the Californian coast are stated to migrate southwards after the breeding-season, and probably cross the equator. *M. leoninus* is characterised by the comparatively long snout of the old bulls, whereas in the Falkland, Crozet, and Macquarie sea-elephants, hitherto identified with *leoninus*, this appendage is shorter. These southern sea-elephants should be known as *Macrorhinus falclandicus* or *patagonicus*, unless the earlier Morunga, or its original and still more barbarous form Mirounga, be preferred.

THE vascular anatomy of mammals forms the subject of the two articles in the November (1909) issue of the *Anatomical Record*, Messrs. Schulte and Tilney discussing in the first the means by which the venous blood is returned to the heart, with especial reference to the iliac veins, while in the second Mr. C. B. Coulter describes the early stages in the development of the aortic arches in the cat, more particularly with regard to the existence of a fifth arch.

The existence in mammals of such a fifth arch, lying between the seismic and pulmonic arches, has recently formed the subject of several papers. This fifth arch appears to be a vessel rising from the aortic bulb and discharging into the pulmonic arch near its junction with the dorsal aorta. It attains fullest development in man and the mole, in both of which it is generally complete, but in the cat and the pig the full arch is rarely formed, while in the rabbit its condition is still more rudimentary.

A LARGE portion of vol. iii., part ii., of the Transactions of the Natural History Society of Northumberland, Durham, and Newcastle is taken up by papers on polypod Arthropoda, Canon Norman and Prof. Brady furnishing a synopsis of the local crustaceans, while Dr. A. R. Jackson comments on rare arachnids obtained in 1908, and the Rev. J. E. Hull contributes notes on spiders. Special interest attaches, however, to the description, by Mr. E. L. Gill, of a new Carboniferous arachnid from the Tyne Valley. This valuable specimen, which was obtained from the Coal-measures of Crawcrook, is evidently related to *Anthracosiro woodwardi*; the two forms agreeing in the general structure of the abdominal region. Whereas, however, the typical species has limbs of a normal type, those of the Crawcrook specimen are curiously expanded and flattened—so much so, indeed, that, unless this peculiar contour admits of some other explanation, it is evident that we have to do with a new species. It has accordingly been named *Anthracosiro latipes*, with the proviso that it may eventually be found advisable to change the generic title.

WRITING in the December (1909) number of the *Zoologist*, Mr. H. St. J. K. Donisthorpe claims to be the fourth naturalist who has witnessed in this country a slave-raid on the part of a colony of *Formica sanguinea*. The incident occurred at Bewdley, and the colony raided belonged to *F. fusca*. At the nest of the latter, the narrator states that "Many workers [of *sanguinea*], laden with pupæ, were streaming off in the direction of their home. . . . Others were attacking and killing solitary *fusca* workers. Several *fusca* workers were observed up the grass-stems, &c., holding pupæ, and endeavouring to escape from the slave-raiders. I watched these proceedings for a considerable time, and accompanied some of the ants with pupæ back to their nest, quite a distance off, though they covered the ground very quickly." In the same nest Mr. Donisthorpe took two "gyandromorph" *sanguiniae*, the one being, both in colour and structure, male on the right side and worker on the left, and the other male on the left and female on the right. Only two other specimens of such abnormal ants, neither referable to *sanguinea*, appear to have been previously observed in Great Britain.

As a large portion of the December (1909) issue of the *Journal of Economic Biology* is taken up by a list of literature and the proceedings of the Association of Economic Biologists, the articles are reduced to two. One of these, by Mr. S. A. Neave, who has recently returned from a prolonged tour in northern Rhodesia, Katanga, and the Congo Free State, relates to the distribution of the species of tsetse known as *Glossina palpalis*. The author remarks that the great Congo-Zambezi watershed forms a delimitation between two quite distinct faunas. On descending from this plateau into the Zambezi basin a fauna of the southern type is encountered, whereas at the same elevation on the Congo declivity the area of the western tropical fauna is entered. Now, so far as is known, *G. palpalis* occurs only on the Congo side, and its distribution coincides with that of the tropical fauna generally. Further, the extent of the range of the species within the tropical area is dependent upon station, the insect first meeting the traveller as he descends from the plateau in the well-wooded, damp gorges cut by the rivers and streams.

CIRCULAR No. 112 of the Bureau of Entomology of the United States describes very fully the Mediterranean flour-moth, and the damage and loss it causes to the milling industry. The pest was first noticed in 1892 infesting several Californian flour-mills, and since then it has gradually spread until at the present day it occurs in practically all the principal milling centres and in most of the States. On attaining full growth the caterpillar forms a new web, which becomes a cocoon wherein it undergoes transformation to pupa, and it is in this stage that the insect does most damage. The infested flour becomes caked, clogging the machinery and necessitating frequent and prolonged stoppage resulting in some cases in the loss of thousands of dollars. The remedy suggested is treatment with hydrocyanic acid; the methods of carrying out this rather delicate and dangerous fumigation, and the subsequent cleaning of the mill, are fully given.

THE Imperial Department of the West Indies has issued a pamphlet on the grafting of cacao, by Mr. Joseph Jones, curator of the Botanic Station, Dominica. It is shown that propagation by grafting gives better results than propagation by seed, inasmuch as the desirable characters of any particular tree, such as character of bean, prolific bearing, early bearing, and resistance to disease, &c., can be reproduced with tolerable certainty. Indeed, in no other way can the planter ensure absolute uniformity of bean, one of the most important features in the improvement of the quality of the crop. Grafted trees always develop into a low, spreading form, and this is of special advantage in picking the pods and also in affording protection from the wind. Full instructions for grafting are given, and the process is shown to be neither difficult nor expensive. Another pamphlet explains how to erect and work cotton gins, and is intended for workmen in regular charge of ginneries and for those who have to erect gins without any previous experience with this class of machinery.

THE "cotton-boll weevil"—a beetle of the genus Anthonomus, to which our own "apple-blossom weevil" belongs—causes in the United States an annual loss estimated at 25 millions of dollars. A vast economic literature has grown up around this insect, the latest contribution being an exhaustive account, by W. E. Hinds and W. W. Yothers, of its methods of hibernation (Entom. Bull., No. 77, U.S. Dept. Agric., 1909). The species is carried over the winter by adult beetles sheltering in various situations—many in old bolls that remain on the cotton-stalks. Only a small proportion of the individuals that commence to hibernate survive until the spring, so that the wintering period affords the most vulnerable stage in the insect's life-history, and detailed information respecting it cannot fail to be of value to the planters who seek some practicable means for destroying the weevils.

THE Year-book of the United States Department of Agriculture for 1908 contains some interesting short articles on the economic importance of vertebrates, written by naturalists attached to the Biological Survey. Mr. F. E. L. Beal discusses the relations between birds and insects, and argues that insectivorous birds are beneficial even though they destroy a large number of predaceous and parasitic insects, since the vegetable-eating insects that are present in any year in abnormally large numbers must form the larger proportion of the birds' food. Mr. A. K. Fisher writes on the economic value of predaceous birds and mammals. He believes that coyotes, foxes, weasels, and skunks are, on the whole, beneficial, and that the most dangerous enemies to poultry are domestic cats. Mr. D. E. Lantz describes the various poisons used for destroying noxious mammals such as wolves, gophers, and prairie marmots, and recommends strychnia-sulphate for general use. This poison is also advocated for campaigns on a large scale against voles by Mr. S. E. Piper, who contributes a paper on "mouse plagues," voles being usually known as "meadow-mice" or "short-tailed field-mice" by American farmers and naturalists.

THE Indian peasant, says the *Pioneer Mail*, usually looks with suspicion upon any scientific innovation which the Government may introduce for his benefit, and it speaks much for the efficacy of the expedient if it eventually overcomes his stubborn prejudices. Such success has attended the inoculation of cattle with rinderpest anti-serum prepared at the bacteriological laboratory of the Civil Veterinary Department. At first great opposition was experienced to the use of the serum, but since it has curtailed outbreaks of a malady which probably creates more havoc than any other cattle disease in India, and has prevented heavy mortality amongst animals, it has been much in demand, and it is now common for cattle owners in infected localities to pay for inoculators to be sent. It is expected that the demand for the serum will increase each year, and the Ceylon Government and many native States desire to be provided with it. The supply is, however, limited. During the year 1908–9 every endeavour was made at the bacteriological laboratory to prepare as large an amount as possible, but about eighty thousand more doses were required than were manufactured.

THE Selborne Society has just issued a new illustrated leaflet entitled "How to Attract Wild Birds." It is a reprint of an article written by the honorary secretary, Mr. Wilfred Mark Webb, for the *Country Home*, and deals with the methods employed in the Brent Valley Bird Sanctuary. A number of photographs which have been used to embellish it were taken in the Bird Sanctuary, and show the construction of the nesting-boxes, the ways of fixing them, the heights at which they should be placed, as well as the open trays which have also been successfully introduced.

IN *Travel and Exploration* for January Mr. P. L. Faulkner gives an account of the Khasia Hills, "a little-known district of the Indian Empire." His description is popular and interesting, but it is curious that he seems to be unacquainted with the valuable official monograph on the Khasi tribe by Major P. R. Gurdon, published by the Government of Eastern Bengal in 1907. By its aid he would have been able to explain the fact, to him mysterious, why a flat stone is placed before the trilithons which the Khasis erect in honour of deceased persons held in respect by the tribe.

IN the December (1909) issue of *Man* Major P. M. Sykes describes the system of tattooing in vogue in Persia. Until the last generation the practice was universal. Now it is rare among persons of rank, and is confined to the lower classes, especially in southern Persia. It seems to be partly ornamental, partly prophylactic. Women use it to avert the evil eye, to hide a scar or other blemish, or to cure disease. As usual, the trade is in the hands of Gypsy women; and though it prevails in Arabia, among the better-class Mussulmans in Persia it is now regarded as a relic of barbarism.

IN *Man* for December (1909) Mr. W. J. Lewis Abbott discusses the so-called "Pygmy" flint weapons. He gives a graphic sketch of the race which erected the Kitchen Middens at Hastings, and is disposed to associate the habit of making these implements with the Continental troglodytes who, he supposes, migrated north to Britain and southwards to the Mediterranean, Egypt, and India. This theory of primitive race migrations obviously involves many difficulties, and it is quite within the bounds of probability that this type of implement may have been independently evolved from more than one centre of origin. The geological evidence collected by Dr. Colley March in Lancashire is believed to show that they belong to an age far more remote than any deposit in which polished stone implements have been hitherto found.

IN the Journal of the Royal Society of Arts for December 17, 1909 (vol. lviii., pp. 101–29), Mr. Hugh Pearson gives a popular account of the diamond fields of Brazil, including the history of the industry since the first discovery of diamonds in 1729, brief descriptions of the geology of the different areas, and the methods of working the deposits. Details are furnished of the curious process of burning out the surface flaws by means of potassium nitrate. The loss in weight is about 8 per cent. There is an excellent general map showing the relative positions of the diamond fields, as well as local maps on a larger scale.

THE constant σ of Stefan's law—the energy radiated by a black body at temperature $T°$ absolute $= \sigma T^4$—has generally been assumed to have the value $5{\cdot}32 \times 10^{-12}$, as deduced by Dr. Kurlbaum from his observations. M. Féry's recent observations give, however, $6{\cdot}3 \times 10^{-12}$. Owing to this disagreement MM. Bauer and Moulin have made a re-determination of the constant by heating a platinum strip *in vacuo* until the radiation from it was equal in amount to that from a perfectly black body at the melting point of gold (1064°). The electrical energy given to the strip was then measured. They deduce as the value of σ to within 1 per cent. $6{\cdot}0 \times 10^{-12}$, and are disposed to question the accuracy of Prof. Planck's expression for the energy of each wave-length sent out by a black body at any temperature. An account of the work is contained in the *résumé* of communications made to the Société française de Physique at the meeting on December 3, 1909.

THE *Physical Review* for December (1909) contains an abstract of a paper on a new modification of the cloud method of measuring the elementary electrical charge, and the most probable value of that charge, read by Prof. R. A. Millikan to the American Physical Society at its Princeton meeting in October. He observes single isolated drops having multiple charges, first when gravity is balanced by a vertical electric field and the drops are stationary, then when the drops fall under gravity, the field having been withdrawn. The mean value deduced from observations of drops composed of water and of alcohol, and having from two to six elementary charges, is $4{\cdot}65 \times 10^{-10}$, with a possible error of 2 per cent. This number is in close agreement with the values obtained by Prof. Planck and by Prof. Rutherford and Dr. Geiger by other methods, but differs widely from those obtained previously by Sir J. J. Thomson, Prof. Townsend, and Prof. H. A. Wilson.

IN the U.S. Geological Survey's Bulletin No. 401, 1909, Mr. George F. Becker discusses the origin of petroleum and other natural hydrocarbons, with numerous references to authorities. He considers it proved that some oils are of organic, others of inorganic, origin. So far, however, as any direct evidence goes, "the great petroleum pools . . . may have been derived from carbonaceous matter of vegetable or animal origin . . . (or) from carbides of iron or other metals." The possibility of the latter origin led Mr. Becker to consult Dr. L. A. Bauer's map of magnetic declination in the United States. This he reproduces, marking on it where petroleum exists, and concludes:—"What the map does prove is that petroleum is intimately associated with magnetic disturbances similar to those arising from the neighbourhood of minerals possessing sensible magnetic attraction. . . . Henceforth no geological theory of petroleum will be acceptable which does not explain this association." Mr. Becker's conclusions, if confirmed, promise a new and important sphere of usefulness for magnetic surveys.

The Patents and Designs Act, 1907, forms the subject of an article, by Mr. George Schuster, in the December (1909) number of the *Economic Journal.* Mr. Schuster deals mainly with the effect which the Act has had upon the practice pursued by some foreigners of taking out British patents for the purpose, not of working them in the United Kingdom, but of preventing them being worked there. He states that there has not been any petition for revocation under Sec. 27 in which the revocation would have led to the establishment of an important industry in the United Kingdom, and points out that this fact, when considered in conjunction with the other evidence, affords conclusive proof that the original evil was greatly exaggerated, and accordingly that the hopes of benefits to be felt on its removal could not in any case have been realised. This conclusion justifies the note of warning given in Nature for July 23, 1908, immediately before Sec. 27 came into operation, in the following words:—"Much has been written lately as to the benefits to this country likely to be produced by this section, and in some cases there has been considerable exaggeration of the probable effects."

Prof. R. H. Smith contributes an article on a new formula for the total heat of steam in the *Engineer* for December 24, 1909. Prof. Smith has been led to analyse the law of total heat algebraically in consequence of the publication of a new set of tables compiled by Prof. L. S. Marks and Mr. H. N. Davis, of Harvard University. These tables are consistent between their different columns, and also seem to give data really trustworthy for comparatively strict accuracy. The formula, which represents with complete accuracy the figures of the new table throughout the whole range from 70° F. to 500° F., is as follows:—

Total heat from 32° F. of saturated steam:

$$H = 1826 + t - \frac{1{,}250{,}000}{1020 - t}.$$

The author gives an abbreviated table for comparison of the tabular numbers given by Marks with the results as calculated by the new formula; the comparison shows very close agreement, excepting for temperatures below 60° F. and above 500° F. It will, of course, be remembered that it is very difficult to make accurate heat experiments on very low-pressure steam, and also that no trustworthy experimental data as yet exists for temperatures above 400° F., the tabular numbers given by Marks having been extrapolated.

In the note on Mr. Knocker's address on the arrangement of ethnological collections in provincial museums in Nature of December 16, 1909 (p. 198), the word *geographical* should have been *non-geographical.*

Messrs. Williams and Norgate will publish almost immediately "Beet-sugar Making and its Chemical Control," by Mr. Y. Nikaido. The author has endeavoured to explain, not only the practical operations of sugar-house stations, but also the fundamental principles involved in the various processes of the sugar house and in the methods for analysis of various sugar-house products.

Messrs. W. and G. Foyle, 135 Charing Cross Road, London, W.C., have just issued a new edition of a classified catalogue of scientific and technical books. The catalogue contains a selection of books which can be supplied both new and second-hand, and, so far as it goes, it should prove of service to students seeking books on particular subjects.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in January:—

Jan. 7. 5h. Venus at greatest brilliancy.
,, 9h. Saturn at quadrature to the Sun.
8. 14h. Neptune at opposition to the Sun.
10. 1h. Mercury at greatest elongation, 19° 2′ E. of the Sun.
11. 0h. 14m. Uranus in conjunction with the Moon (Uranus 3° 9′ N.).
,, 18h. Uranus in conjunction with the Sun.
12. 9h. 12m. Mercury in conjunction with the Moon (Mercury 4° 33′ N.).
13. 15h. 22m. Venus in conjunction with the Moon (Venus 7° 43′ N.).
16. 12h. Mercury stationary.
17. 3h. 45m. Saturn in conjunction with the Moon (Saturn 1° 34′ N.).
,, 16h. Mars at quadrature to the Sun.
,, 19h. 19m. Mars in conjunction with the Moon (Mars 4° 25′ N.).
20. 2h. Venus stationary.
23. 16h. 5m. Neptune in conjunction with the Moon (Neptune 4° 5′ S.).
29. 21h. Jupiter stationary.
30. 12h. 5m. Jupiter in conjunction with the Moon (Jupiter 2° 45′ S.).

Halley's Comet.—The following is an extract from the corrected ephemeris for Halley's comet published by Mr. Crommelin in No. 4379 of the *Astronomische Nachrichten*:—

Ephemeris for Greenwich Noon.

1910	R.A. h. m.	Decl. ° ′	log r	log Δ
Jan. 5	2 4·6	+10 56	0·2984	0·1568
10	1 49·4	+10 15	—	0·1704
15	1 36·2	+ 9 39	0·2664	0·1851
20	1 24·7	+ 9 9	—	0·2001
25	1 14 9	+ 8 45	0·2310	0·2147
30	1 6·4	+ 8 27	—	0·2284

Thus we see the comet is about to pass from Aries into Pisces, and may be observed, with a sufficiently powerful instrument, at any time during the evening before midnight.

Observations made at Utrecht on November 8, 13, 17, 19, and 21, 1909, by Drs. Nijland and J. v. d. Bilt, indicated the increase of brightness shown by the following magnitudes:—13·5, 13·0, 12·8, 12·8, and 12·7.

Elements and Ephemeris for Daniel's Comet, 1909*e*.—In No. 4379 of the *Astronomische Nachrichten* Dr. Ebell gives a set of new elements and an ephemeris for Daniel's comet, 1909*e*. From these we learn that perihelion passage occurred on 1909 November 27·6694 (M.T. Berlin), and that the comet is now but little more than half as bright as it was at the time of discovery. Its position for

January 6 is $\alpha=6$h. 18·5m., $\delta=+53° 48{\cdot}1'$, and it is still moving northward slowly.

Solar Activity and Magnetic Storms.—No. 1, vol. lxx., of the Monthly Notices (November, 1909) contains three papers on the connection between solar activity and magnetic storms.

In the first, Dr. W. J. S. Lockyer discusses a series of spectroheliograms taken at the Solar Physics Observatory, South Kensington, and shows that the enormous magnetic disturbance of September 25, 1909, was preceded by an abnormal outburst in connection with a spot then on the sun. One of these photographs shows that at about 10 a.m., September 24, the calcium flocculus surrounding the spot was so disturbed as to obliterate the very fine nuclei seen on the preceding photographs; these nuclei reappeared on a negative taken at 11h. 11m. the same morning.

The time of the maximum magnetic disturbance appears to have been 4h. 30m. p.m. on September 25, showing a "lag," after the solar disturbance, of about 30·5 hours. In a similar case, in 1892, Prof. Hale found that the "lag" was about 25·3 hours.

In the second paper, Father Cortie deals generally with the recent solar and magnetic disturbances, and points out that this spot was not accompanied by any abnormal, visual, spectroscopic outburst commensurable in intensity with the magnetic disturbance.

In the last paper Mr. Michie Smith shows, from the evidence of the spectroheliograms and magnetograms secured at the Kodaikánal Observatory, that a great eruption about a spot photographed on September 28, 1909, was accompanied by a magnetic disturbance.

Star Swarms.—In an article which appears in the current *Fortnightly Review* (p. 140), Prof. Turner gives a very interesting and lucid popular account of "Migrating Stars."

The difficulties and results of Prof. Boss's work in showing that a number of stars in Taurus are moving together, apparently to a convergent but really along parallel paths, are clearly explained and illustrated by some attractive analogies. This cluster is now some 120 light-years from us, and occupies a space on the celestial globe comparable with that occupied by India on the terrestrial; but in about 6[illegible] million years it will have receded so far as to appear merely as a star cluster, occupying an area, using the same analogy, about equal to Anglesea.

The researches of Dr. Ludendorff on the related stars of Ursa Major, and of Dr. Hertzsprung, who has added Sirius, α Coronæ, and other stars to it, are also described.

In No. 4366 of the *Astronomische Nachrichten*, Herr Kostinsky directs attention to two swarms of stars in the neighbourhood of the star clusters χ and h Persei, the individual members of which appear to partake of motions in a common direction.

A Large Nebula in Cetus.—On a plate taken in the autumn by Herr Lorenz, Prof. Wolf found traces of a large patch of nebulous matter in the constellation Cetus, and has recently succeeded in photographing it with the Waltz reflector. The negative obtained, with two hours' exposure, shows that the object is a long streak running in the N. and S. direction, its length being 15′; at the broadest part, E. and W., its breadth is 3′. The position of the central part of the nebula is $\alpha=23$h. 54·6m., $\delta=-16° 15'$ (1855·0), and the whole is seen to be a conglomeration of smaller nebulæ (*Astronomische Nachrichten*, No. 4380, December 28, 1909, p. 187).

Annuaire astronomique et météorologique, 1910.—For the amateur observer conversant with French, there are few more useful volumes than M. Flammarion's "Annuaire." This year's issue is very similar to its predecessors, but contains a useful *résumé*, with many drawings, of the observations of Mars during the recent opposition. Solar observers, wishing to chart sun-spots, will find the "Disques Moreux," figured on p. 67, a useful adjunct to their outfit. The climatology of 1908 is reviewed, and at the end of the volume there are some useful instructions on the use of instruments for people commencing astronomical observation.

PRIZE AWARDS OF THE PARIS ACADEMY OF SCIENCES.

At the annual public meeting of the Academy of Sciences, the president, M. Ch. Bouchard, delivered the annual address, dealing with the population question in France, and announced that the prizes for the year 1909 had been awarded as follows:—

Geometry.—The Francœur prize to Émile Lemoine, for the whole of his works; the Bordin prize to G. Bagnera and Michele de Franchis, for their memoir on the number ρ of M. Picard for hyperelliptic surfaces.

Mechanics.—A Montyon prize to M. Lecornu, for his book on applied dynamics; the Poncelet prize to M. de Sparre, for the whole of his works; the Boileau prize to M. Boulanger, for his treatise on hydraulics. No satisfactory memoirs having been received on the subject proposed for the Vaillant prize, this has been postponed until 1911.

Navigation.—The Prix Extraordinaire de la Marine divided between M. Marbec, for his memoir on the theory of the equilibrium of an elastic plate submitted to a uniform pressure; M. Doyère, for his work on submarines; M. L. J. H. Lecoq, for work on the stability of submarines; MM. Victor Colin and Jeance, for their work on wireless telephony; M. Tissot, for work on wireless telegraphy; and M. E. Fromaget, for his river survey work in eastern French Africa. The Plumey prize between M. Routin, for his work on the regulation of electrogenic groups, and M. Henry Caralp, for his book on boilers and engines in warships.

Astronomy.—The Lalande prize to M. Borrelly, for his work as a whole; the Valz prize to M. de la Baume-Pluvinel, for his work on solar eclipses and the constitution of comets; the G. de Pontécoulant prize to Prof. E. W. Brown, of Yale, for his work on the theory of the moon. The Pierre Guzman prize was not awarded, and the Damoiseau prize postponed until 1911, no memoirs having been received on the subject proposed.

Geography.—The Tchihatchef prize was not awarded, but M. Henry de Bouillane de Lacoste receives a very honourable mention (2000 francs); the Gay prize to M. L. Joubin, for his researches on the distribution of marine plants in the Roscoff region.

Physics.—The Hébert prize to M. Paul Janet, for his book on general electrotechnics; the Hughes prize to M. Meslin, for his researches in physical optics, magneto-optics, and physical astronomy; the Gaston Planté prize to M. Jean Perrin, for his researches on the kathode rays and on the Brownian movement; the La Caze prize to M. Léon Teisserenc de Bort, for his contributions to meteorology and physics of the globe.

Chemistry.—The La Caze prize between M. G. Blanc, for his researches on the derivatives of camphor, and M. Marcel Guerbet, for his contributions to organic chemistry; the Cahours prize between MM. Carré, Jolibois, and Brunel; Montyon prize (unhealthy trades) to MM. Émile Lefranc, Paul Letellier, and Maurice Perrot; the La Caze prize to M. Recoura, for his work on chromium compounds.

Mineralogy and Geology.—The Grand prize of the physical sciences to M. A. Thévenin, for his memoir on the stages of evolution of the most ancient quadrupeds found in France; the Delesse prize to M. Ph. Glangeaud, for his contributions to the geology of the Auvergne; the Victor Raulin prize (1908) to M. Léon Bertrand, for his contribution to the stratigraphical and tectonic history of the eastern and central Pyrenees, and (1909) to M. Ferdinand Gonnard, for his mineralogical researches; the Joseph Labbé prize to M. Georges Rolland, for his geological studies relating to the mine basin of Meurthe-et-Moselle.

Botany.—The Desmazières prize to M. l'Abbé Hue, for his researches on lichens; Montagne prizes to MM. H. and M. Peragallo, for their work on French marine diatoms, and M. Guilliermond, for his researches on the structure of the Cyanophyceæ and bacteria; the de Coincy prize to M. René Viguier, for his work on the Araliaceæ; the Thore prize to M. Paul Bergon, for his researches on the structure and development of diatoms.

Anatomy and Zoology.—The Savigny prize to M. Robert du Buysson, for his entomological studies in Egypt; the da Gama Machado prize to MM. J. Pantel and R. de Sinéty, for their studies in spermatogenesis; the Cuvier prize to M. Charles Janet, for his anatomical and embryological researches on ants.

Medicine and Surgery.—Montyon prizes to MM. Neumann, Ch. Nicolle, Bergonié, and Tribondeau, mentions being accorded to MM. Moussu, H. Truc and P. Chavernac, Ch. Porcher and Ch. Hervieux, and a citation to MM. Henri Claude and Jean Camus. The Barbier prize between M. L. Launoy, for his researches on the conditions of activity of glandular cells, and M. J. Lesage, for his experimental studies on maté (*Yerba maté*). The Breant prize was not claimed, but from the interest of the fund a prize of 4000 francs was awarded to W. M. Haffkine, for his work on vaccination against cholera and plague, and a mention of 1000 francs to M. Louis Rénon, for his memoir on the practical treatment of pulmonary tuberculosis; the Godard prize to M. A. Pousson, for his work on the surgery of nephritis, and a very honourable mention to M. J. L. Chirié, for his studies on arterial hypertension; the Baron-Larrey prize to M. Niclot, for his researches on the relations between the numbers of Anopheles and cases of malaria in the Oran district, and a very honourable mention to MM. Dupard and Lepourcelet, for their contribution to the study of meat in the army; the Bellion prize to M. Ch. Nicolas, for his work on public and private hygiene in the Loyalty Islands; the Mège prize (interest) to M. S. J. Metalnikoff, for his researches on *Galleria mellonella*; the Parkin prize to M. Ad. Cartaz, for his therapeutical studies on carbon dioxide as applied to diseases of the nose and throat.

Physiology.—Montyon prizes to M. Charles Dhéré, for his spectrographic researches on the absorption of the ultra-violet rays by albumenoids, proteids, and their derivatives, and to M. E. Pozerski, for his contribution to the physiological study of papaine; the Philipeaux prize to MM. J. E. Abelous and E. Bardier, for their discovery of urohypertensine; the Lallemand prize between M. August Pettit and Gustave Roussy; the La Caze prize to M. C. Delezenne, for the whole of his researches in physiology. The Pourat prize was not awarded, and is postponed to 1911.

Statistics.—A Montyon prize to M. Louis de Goy, for his financial studies, M. Ausset receiving an honourable mention.

History of Science.—Binoux prizes to M. P. Duhem, for the whole of his works relating to the history of science, and M. J. B. de Toni, for his historical studies on the life and work of Italian philosophers of the fifteenth and sixteenth centuries.

General Prizes.—Berthelot medals to MM. G. Blanc, Marcel Guerbet, Jolibois, Brunel, Émile Lefranc, Paul Letellier, Maurice Perrot; the Gegner prize to M. J. H. Fabre; the Lannelongue prize to Mme. Cusco and Mme. de Nabias; the Trémont prize to M. Charles Frémont; the Wilde prize to M. Joseph Vallot, for his work on Mt. Blanc; the Longchampt prize to M. Claudius Roux, for his work on the chlorosis of plants; the Saintour prize to MM. E. F. Gautier and R. Chudeau, for their scientific studies in the Sahara; the Jean Jacques Berger prize between MM. Bienvenue (3000 francs), Biette (1000 francs), Locherer (1000 francs), Thomas (1000 francs), Faillié (750 francs), Hervieu (750 francs), Chagnaud (750 francs), Daydé and Pillé (750 francs), and Calmette (6000 francs). The Petit d'Ormoy prizes were not awarded. M. E. Mercadier receives the Pierson-Périn prize for his physical researches; M. Ritz and M. Lebeuf, 2000 francs each from the Leconte fund; M. Vaucheret, the prize founded by the Marquise de Laplace; and MM. Vaucheret, Hentschel, Messiah, and Courtaigne the prize founded by M. Felix Rivot.

The Bonaparte Fund.—The committee proposes the following grants from this fund for the year 1909:—M. Cayeux, 4000 francs, to enable him to follow up in the United States his researches on oolitic iron-ore deposits, already commenced in France; M. Chevalier, 4000 francs, to assist his explorations in tropical Africa; M. Pérez, 4000 francs, to assist in the publication of a memoir entitled "Recherches histologiques sur les Métamorphoses des Muscides"; M. Houard, 3000 francs, to enable him to travel in Corsica, Algeria, and Tunis for the purpose of collecting material; M. Berget, 2000 francs, for the construction of a special form of pendulum for studying the variations of gravity; M. Bernard, 2000 francs, to assist him in his photometric studies of the variations of solar radiation; M. Blaringhem, 2000 francs, to enable him to continue his experimental researches on the variation of species; M. Estanave, 2000 francs, to permit him to continue his researches on stereoscopic vision, stereoradiography, and autostereoscopy; M. Mathias, 2000 francs, to enable him to continue his researches at the Leyden cryogenic laboratory on the rectilinear diameter of liquids and on the law of corresponding states at very low temperatures.

The academy, taking advantage of the freedom accorded it under the terms of the Petit d'Ormoy foundation, has decided this year not to give this prize in the usual form, but to strike medals commemorative of the progress made in flying. Gold medals have accordingly been awarded to Louis Blériot, Commandant Bouttieaux, Captain Crocco, Henri Farman, Captain Ferber, Henri Juilliot, Charles de Lambert, Hubert Latham, Léon Levavasseur, Col. Charles Renard and Commandant Paul Renard (one medal), Alberto Santos-Dumont, Rodolphe Soreau, Édouard Turcouf and Henri Kapferer (one medal), Léon Teisserenc de Bort, Henry de La Vaulx, Gabriel Voisin, Commandant Jules Voyer, Orville Wright, Wilbur Wright and Count de Zeppelin. Also silver-gilt medals to Gustave Hermite and Georges Besançon, Louis Breguet, Léon Delagrange, Robert Esnault-Pelterie, L. Marchis, Louis Paulhan, Henri Rougier, and Victor Tatin.

CLIMATOLOGICAL REPORTS.

THE director of the meteorological observatory at Chemulpo has issued the results of the observations made at the Japanese meteorological stations in Korea for each of the months January–December, 1908. The instruments and the method of observation are the same as those at the meteorological stations in Japan, and the readings, taken six times a day, are expressed in metric and centigrade measures, with monthly means and extremes. These form an important contribution to the meteorology of the Far East; their value would be much enhanced by the addition of annual summaries.

The report on rainfall registration in Mysore for 1908 shows that, except in the Shimoga (north-west) district, the amount was deficient in all parts of that important province, reaching 43 per cent. in Kolar (east). The deficiency of the fall during both monsoons was detrimental to the cultivation of ragi, which is the staple dry crop of the province. The tables for monthly, seasonal, and yearly periods have been carefully prepared by Mr. Iyengar, as before, with diagrams and maps showing (1) the annual rainfall for 1908, and (2) the average for 1870–1908. The mean amount for the whole province in 1908 was 29·94 inches, the average for the thirty-nine years' period being 36·79 inches. Among the heavy daily falls we note 11·22 inches in Shimoga district, and 10·90 inches in Kadur district, both in the month of July.

An important memoir on the climate of Tripoli is published in the Annals of the Italian Central Meteorological Office (vol. xxx., part i.), containing the results of observations made during the years 1893–1907, at an observatory established by the Italian Foreign Office and the Meteorological Service, and situated in lat. 32° 54′ N., long. 13° 11′ E. The mean monthly values of atmospheric pressure exhibit the greatest variability during the winter season, when the barometer is highest; the lowest readings occur during spring. The mean monthly temperatures do not show much variation from one year to another. The means of the daily maxima are 60·0° in January and 86·2° in August, and of the minima 46·1° in January and 72·9° in August. The absolute maxima and minima were 109·0° in July and 34·5° in January. The mean annual rainfall is 17·29 inches, most of which falls between October and February (14·85 inches); from June to August inclusive little or no rain falls. The memoir has been carefully prepared in considerable detail by Profs. Martinuzzi and Eredia, and is especially valuable, as comparatively little has hitherto been published on the climatology of that country.

In the annual summary of the *India Weather Review* for 1908 the observations included in monthly issues are discussed in detail, and the departures of the monthly and annual means from the normal values are calculated for each element. Dr. Walker states that, on the whole, 1908 was cooler than usual, although in April and June, both of which were dry months, the temperature was in decided excess of the normal. Excluding the hill stations, 1908 was a year of average rainfall; of the four seasons, the cold weather and south-west monsoon were more rainy than usual, while the other two periods were markedly dry. With respect to the monsoon rainfall, the character was opposite to that prevailing in the previous seven years, all of which were in defect. The most striking feature of the year was the heavy rainfall in the dry zone of north-west India, due to the strong monsoon currents in July and August.

The report of the Transvaal Meteorological Department, containing observations and results in the usual form for the year ended June 30, 1908, has been received. The number of rainfall stations has greatly increased, and includes those which formerly reported to the Irrigation Department. The rainfall was below the average generally; at Pretoria the deficiency amounted to 31 per cent., and at Johannesburg to 10 per cent. Farmers suffered from want of water, but, among the compensating factors, remarkable freedom from locusts and little damage from hailstorms are mentioned. In connection with this report we may refer to interesting contributions by Mr. Innes (director) and Mr. Wood (chief assistant) to the climatology of the Transvaal in the current number of the Journal of the Scottish Meteorological Society. Mr. Innes remarks that it is one of the sunniest climates inhabited by civilised races, the average cloudiness being about 30 per cent., and the relative humidity low. Speaking of the High Veld generally, which is at an elevation of about 4000 feet, it is warm by day and cool at night. The rainfall averages 25 to 30 inches, the number of days with rain being only about eighty-five. At places like Johannesburg (5750 feet) the cold during winter is considerable, owing more to the cold wind than to actual temperature. Over the latter (Witwatersrand) district Mr. Wood shows that the mean monthly rainfall increases with great regularity from July (0·11 inch) to January (5·80 inches), and then diminishes to June (0·09 inch). The probability of heavy rainfalls (1 inch and above) is entirely confined to the months October–March inclusive.

The Department of Agriculture, Nairobi, has issued its fifth annual report of meteorological records in British East Africa, containing monthly rainfall values for fifty-six stations during 1908, and averages for ten years (1899–1908) and under at twenty-five stations. The latter show that the mean annual rainfall varied from about 16 inches at Kismayu to 72 inches at Mumias. Meteorological summaries for 1908 are given for ten stations; so far as these show, the absolute extremes of temperature were 99° at Nandi (6000 feet above sea) in February, and 35° at Elmenteita (height not stated) in January.

The Weekly Weather Report issued by the Meteorological Office, London, for the period ending January 1 contains a summary of temperature, rainfall, and bright sunshine for the year 1909. From this it is seen that for the fifty-two weeks ending January 1 the temperature was below the average over the entire kingdom. The rainfall was in excess of the average in all the English districts except in the south-west, but it was generally deficient in Scotland and Ireland. The largest aggregate measurement of rain is 47·12 inches, in the west of Scotland; the least amount for the year is 26·04 inches, in the east of England. The greatest excess of rain is 5·21 inches, in the south-east of England, and the greatest deficiency 6·91 inches, in the north of Scotland, whilst in the north of Ireland the aggregate measurement was 5·53 inches deficient. The rainy days were in excess of the average over the entire country, except in the west of Scotland and in the English Channel. The greatest excess was twenty-two days, in the east of England. The greatest number of rainy days was 250, in the north of Scotland, and the least 186, in the south-east of England. The duration of bright sunshine for the year was in excess of the average over the whole of the British Isles, except in the north-east of England, where there was a deficiency of forty-three hours. The greatest excess was 146 hours, in the south-east of England. The longest duration of bright sunshine was 1975 hours, in the Channel Islands, and this was followed by 1743 hours in the south-east of England. The least duration was 1157 hours, in the north of Scotland, which, however, is forty-eight hours more than the average. The mean temperature at Greenwich for 1909 is 48·9°, which is 1·2° below the average of the past sixty years. The highest monthly mean is 62·7°, in August, the lowest 37·2°, in February. The temperature was below the mean in every month except in January, April, October, and December. The absolutely highest temperature was 86°, in August, the lowest 14°, in March, which gives a range of 72° in the year. The temperature was above the average on 144 days, and frost occurred on sixty-five nights, fifty-two of which occurred in January, February, March, and December. The total rainfall for the year was 25·71 inches, which is 1·58 inches more than the average of the last sixty years. The wettest months were June, July, and March, in each of which the total fall exceeded 3 inches. In all, rain fell on 186 days, December having as many as twenty-three wet days and March twenty-two. There were during the year 1637 hours of bright sunshine at Greenwich, which is 138 hours more than the average. The sunniest month was May, with a record excess of 140 hours. Snow fell on twenty-four days and fog occurred on forty-three days during the year.

EDUCATIONAL TENDENCIES IN THE UNITED STATES.

THE first volume of the report of the U.S. Commissioner of Education for the year ended June 30, 1909, has now been published, and is consequently available at an earlier date after the conclusion of the year with which it deals than any previous report. The second and concluding volume of the report is to be issued early in March next.

The present instalment, which runs to 598 pages, is prefaced by an introduction by the Commissioner, Dr. E. E. Brown, which gives a brief *résumé* of the more important subjects dealt with at length in the succeeding chapters. It is possible here to refer to a few only of the numerous subjects of interest discussed in the volume.

Industrial education has commanded attention in all parts of the States during the past year. The report points out that it has become increasingly evident that one of the vital elements of the problem, so far as the United States are concerned, is the question of the relation of school training to shop practice or apprenticeship. Accounts are given of several experiments which are being tried in various States. The special combination of shop practice with regular scholastic training, which was introduced two or three years ago by the University of Cincinnati, is receiving much attention, and a modification of this plan has been carried into effect in the public schools of Fitchburg, Mass. Model and practice schools have been provided for the teaching of manual arts in connection with the State normal school in Fitchburg. A cooperative course in preparation for the metal trades has been introduced into the Lewis Institute, in Chicago, for boys from sixteen to twenty years of age. Each boy in each of the two years of this course spends twenty-six weeks in the shop and twenty-four weeks in school, receiving from his employer the school tuition fee of 10*l.* a year and 1*l.* a week for the time he works in the shop. The report emphasises the fact that many diverse and often opposing interests are concerned in the effort to work out an American system of industrial education. All these interests are to be given full and fair consideration, and it is being borne in mind that, to render such a system stable and altogether American, it must be made genuinely educational.

Agricultural education has been stimulated during the year by the inquiries and the report of the Commission on Country Life, appointed by President Roosevelt. The establishment of agricultural high schools in different parts of the country goes forward steadily. Mississippi and Arkansas have made important beginnings in the establishment of such schools during the year, and Minnesota has provided for agricultural departments in the graded schools of the State.

Referring to American colleges and universities, Dr. Brown gives it as his opinion that among the leaders of American university education there is a growing and surprisingly unanimous conviction regarding the directions in which improvement should be made in higher education in the States. It is to be rendered more coherent, vital, and democratic. As President Butler has remarked:—"The American college is under fire, no doubt. Well-directed intelligent firing will do it good. It is far from perfect, but it knows its job, and is working at it with the skill born of long and successful experience." The democratic movement in higher education has been emphasised during the year by the effort to organise in Massachusetts an institution which shall bring courses of college instruction home to all communities in the State in which it may be desired—a project which has been referred by the Legislature to the new State Board of Education for an opinion as to its advisability; by the step taken by Cornell University in the direction of the State university form of organisation, and by the beginnings at the University of Wisconsin of a more comprehensive and widely diffused system of university extension.

Within the year the University of Wisconsin has been a centre of public interest in a variety of ways, not the least important of which is the Vilas bequest, which is expected to amount to 400,000*l*., and to be administered so that it shall eventually reach a total of 4,000,000*l*. The fact that the available income of this fund is to be devoted largely to research renders it an epoch-making endowment.

In addition to its treatment of the problems of American education, the volume provides an admirable series of summaries of educational progress in European and other countries. Separate chapters are devoted to educational problems in Hawaii, the Philippines, Porto Rico, the Argentine Republic and Chile, Great Britain and Ireland, France and Central Europe. Educational reform in China and current educational topics in foreign countries each receive special treatment.

These educational reports from Washington have often been praised in these columns, and it will suffice to say that the latest report fully maintains the excellence of its predecessors.

OLE RÖMER AND THE THERMOMETER.[1]

THE first thermometers of which the indications were independent of atmospheric pressure appeared in the latter half of the seventeenth century, but Fahrenheit was the first one to succeed, in 1710, in solving the problem of furnishing these thermometers with such scales that their indications agreed; these thermometers were much admired, and represented great progress. It may therefore be of interest to show that Ole Römer solved this problem before Fahrenheit, and that it was from him that Fahrenheit obtained his method.

From some stray remarks which I happened to come across in scientific literature of the eighteenth century, I saw that Ole Römer probably occupied himself with the construction of thermometers, and that some connection existed between him and Fahrenheit. These statements had the effect of inducing me to look for traces of Römer's work in the libraries and archives here in Copenhagen. In the university library I found what I was looking for—a work by Römer called "Adversaria," a volume of written papers in folio bound in a brown cover.[2]

The book contains a whole section about the thermometer, besides some scattered statements about temperature measurements, which I shall return to later. The arrangement of Römer's thermometer seems to me to be of considerable interest. Römer appears to have been the first to construct thermometers with the two fixed points, the temperature of melting snow—"Nix sine gelu et calore"—and the boiling point of water, and with the cubic contents of the tube divided into equal parts. Both Römer and Horrebow's remarks seem to indicate that this took place about the year 1702. The first part of this section is mathematical, and deals chiefly with the problem of dividing the cubic contents of a conical glass tube into equal parts. Römer finds a general method of making such a division, and calculates approximate formulas by the aid of which he may carry out more easily his calculations; he employs these formulas in dividing the cubic contents of a conical tube 8 inches long, intended for his "original thermometer," into four equal parts, and he gives the length of these parts when he determines that the scale of the thermometer is to have sixty divisions, and these are to be arranged in such a way as to read "boiling 60, snow without cold or warmth $7\frac{1}{2}$." After these preliminary investigations Römer gives complete instructions in four paragraphs for "the construction of an original[1] thermometer."

"(1) By means of a drop of mercury investigate whether the cavity of the tube, be it cylindrical or conical, is regular before the ball is blown out. Irregular forms are to be rejected; the cylindrical form may be employed without further investigation. With regard to the conical forms, proceed as follows:—

"(2) From the middle of the tube towards the outer points take the lengths of the drop of mercury.

"(3) When by means of this experiment the divisions have been divided into two equal parts, each of these parts is in turn divided into two equal parts proportionally by increase or diminution, and the whole tube will thus be divided into four equal parts.

"(4) When the thermometer is completed, filled and closed, fix by means of snow or crushed ice the point of division $7\frac{1}{2}$, by means of boiling the point 60."

After these instructions there are remarks written in Horrebow's hand and with his signature which are supplementary, and show also that Römer's thermometer existed after his death (1710):—"... In 1739, Römer's widow sent me five glasses for thermometers which Römer himself had filled and divided with two points in accordance with his own rules given above. The alcohol in them is rather pale, although Römer coloured it with saffron in the usual manner. ... After this was written, I asked Römer's widow if she knew whether Römer, after I had left his observatories, had made any change in his thermometer. She said that she did not know, but she gave me Römer's *vade mecum*, in which I found a loose sheet, which is pasted in here after the next sheet. On that I read that Römer fixed upon 8 as the dividing-point for snow, and thus, so far as we know, the alcohol never sinks below 0 in Copenhagen, and it is to be remarked that January 7, 1709, the alcohol only sank to $7\frac{6}{10}$."

The loose sheet which Horrebow mentions contains a table of temperatures which gives the temperature for every day from December 26, 1708, to April 1, 1709.

The two following pages contain a sort of table of corrections for the four divisions.

After this short account of the contents of the eleven folio pages which Römer devoted to the construction of his "new" thermometer, it will be appropriate here to give a short explanation of his method and to point out what is new in it.

The chief feature of the method is this: to base the division of the thermometer on two fixed points, the melting point of thawing snow and the temperature of boiling water, and to find the length of the degree by dividing the cubic contents of the thermometer tube between these two points into equal parts, taking into consideration whether the tube is cylindrical or not. The size of the degree is obtained on the basis of the fact that there must be between the freezing point and the boiling point 52·5 degrees of equal cubic content. If the tube is cylindrical the whole length between the two fixed points is divided into $52\frac{1}{2}$ equal parts, and 7·5 similar parts are added below the freezing point, zero being thus determined. If the tube is not cylindrical, but conical, an investigation of the dimensions of the tube is made according to the method described in the introduction, the result obtained being the relation between the length of that part of the tube enclosing the seven-eighths of the cubic contents nearest the boiling point and the whole length which is to be employed for the 60°; in the example which Römer takes the conditions are such that the length of the tube between the boiling point and the freezing point must be divided into 52·2 equal parts, 7·8 parts to be added below the freezing point, zero thus being obtained. In using such a thermometer with a conical tube, it is necessary to have a table giving the readings in terms of degrees; thus the reading 7·8 on the length of the tube meant, in terms of Römer's thermometer, 7·5°, 15·563 meant 15°, &c.

---

[1] v. Kirstine Meyer: Temperaturbegrebets Udvikling gennem Tiderne og dets Forhold til vekslende Anskuelser om Varmens Natur. Gjellerups Boghandel. Inaugural Dissertation. (Copenhagen, 1909.)

[2] The language in "Adversaria" is chiefly Latin; the book will be published in 1910 under the auspices of the Kgl. danske Videnskabernes Selskab.

[1] Some weights which are still in existence from Römer's time, and probably are those that he constructed as standards for the new system of weights and measures introduced by the Act of May 1, 1683, bear the inscription "original weight." From this it may be inferred that "original thermometer" means "standard thermometer," and that it was Römer's purpose to introduce a standard for thermometers as for other units of measure.

Three questions naturally arise when we see that Römer used so much of his limited time in constructing on "original" thermometer:—(1) Is this interest in any way connected with the rest of his scientific or practical work? (2) Did he use the thermometers thus constructed for systematic measurements? (3) Have his new ideas in this line contributed anything to the improved construction of thermometers on the whole? In "Adversaria" there are indubitable indications that the first two questions are to be answered in the affirmative; he gives very excellent results of experiments on "the change of length in metals caused by cold and heat," and, furthermore, there is a sketch of an apparatus for comparative measurements of the expansion of gases and liquids when exposed to heat, and some good results of these measurements. There is also, as already mentioned, a series of measurements made with the new thermometer of the temperature of the air in Copenhagen during the winter of 1709. These measurements are of special interest, and are mentioned several times in the literature of foreign countries. The winter of 1709 was very severe. In an article in Phil. Trans., No. 324, 1709, W. Derham writes, in "The History of the Great Frost in the last Winter," about the conditions in Denmark:—"Dr. Woodward tells me, that in a lettre, he received from the learned Mr. Otto Sperling from Copenhagen, dated April 6, 1709, he calleth it Hyems Atrocissima. And I find it noted in the Minutes of the Royal Society of May 4, 1709. That Dr. Judichar said the ice was frozen in the harbour of Copenhagen 27 inches, and that April 9 N.S. people had gone over between Schone and Denmark on the ice. Which accounts give me a better opinion of some papers I have by me which were shew'd to the Society, concerning the frost at Copenhagen pretended to be taken from the observations of Mr. Römer. I should not entertain any the least distrust of the accuracy either of the instruments or observations of that eminent person were I sure they were his. But there are some passages and hints in those papers that lessened others as well as my opinion about them. 'Tis said there 'That such a frost hath not been known in the memory of man of these countries and *that*[1] *the frost on January 7 and February 23, 170$\frac{8}{9}$, did very nearly approach the Point of Artificial Freezing.*'" If we now look at the table of Römer's temperature observations from 1708–9 which is found in "Adversaria," it will be seen that it begins December 26, 1708, and continues until April 9, 1709, only that after April 1 there are not observations for every day, and this is no doubt due to the fact that the table is only calculated to show temperatures under 8°. The remarks along the margin are written in Horrebow's hand. The first remark is:—"So Römer had changed his first plan." The meaning of this is, as may be seen from Horrebow's other remarks in "Adversaria," that he thinks that Römer had placed 8 at the melting point instead of 7½ as earlier.

Now the table shows that on February 23, exactly the date which Derham especially mentions, the thermometer went down to about Römer's zero. It is important to note the exact wording of Derham's remark, "that the frost, February 23, 170$\frac{8}{9}$, came near the temperature for artificial freezing." So it is evidently taken for granted here that *Römer's zero was the temperature of a freezing mixture*, a fact which Derham must have obtained from the report sent from Denmark, since he was not acquainted with Römer's scale. This remark is of special importance for the question as to whether, and if so through what channels, Römer's thermometer has had any widespread influence. The answer is in the affirmative, and the way in which Römer exercised a wide influence was through his influence on Fahrenheit. I shall now proceed to prove that such an influence was exercised by Römer.

In the first place, there are some direct statements about this matter. The most important is by Boerhaave, who, in writing about Fahrenheit's thermometer, says:—"Now it is said that the eminent mathematician Römer in the year 9 of this century observed in Danzig a winter-cold down to the first degree of *this same* thermoscope, of which he himself was the first inventor. Then he increased it with 32° below the freezing-point."

So here it is stated quite distinctly that Römer was the first inventor of Fahrenheit's thermometer; and importance is to be attached to Boerhaave's words about this matter, because he was closely connected with Fahrenheit, who had constructed his thermometers, and whose skill as an instrument-maker and experimenter he often speaks of in terms of praise. That Römer should have made measurements in Danzig in 1709 must be a mistake, which can easily be accounted for by the fact that there are accounts of measurements made in Danzig the same winter with a similar thermometer. At least, I have not been able to find any indications that Römer was in a foreign country at the time mentioned, and his many official duties, his delicate health, and that very list of temperatures for Copenhagen which was sent to the Royal Society make it improbable that he was away from home.

On the other hand, it is related in a biography[1] of Fahrenheit, written four years after his death, that after 1706 he made many difficult journeys by sea and by land, and conferred with the most famous mathematicians in Denmark and Sweden; it is probable that Ole Römer was one of the famous men whom he visited, and then Fahrenheit must have visited him just at the time when the "original thermometer" was used; if Boerhaave's statement is correct, it must be possible to trace Römer's influence on Fahrenheit's thermometers. What Fahrenheit could learn from Römer was chiefly the principle of the two fixed points as a basis for the thermometer scale. According to Fahrenheit's own brief account[2] of his method in the construction of his thermometers, he does, in fact, use fixed points as a basis for his scale, but he mentions three: the temperature of the freezing point, the temperature of a cold mixture, and the temperature of the healthy human body; the last, however, is apparently only used as a sort of check, because Fahrenheit does not wholly rely on the constancy of the temperature of the cold mixture. Now Fahrenheit probably took the two fixed points from Römer, since the zero of Römer's scale, as was evident from Derham's account, was identified with the temperature of a cold mixture, and it appears that the scales of several of the oldest of Fahrenheit's thermometers have the same numeration as Römer's. These thermometers are mentioned in various places; Grischow[3] especially has a full comparison of the somewhat varying scales which Fahrenheit used at different times.

According to Grischow[4] and others,[5] Fahrenheit is said to have confided to his tutor in mathematics, Barnsdorf (from Rostock), the secret of the method of division used on his thermometer, which he maintained was such that anyone who knew it could construct thermometers which agreed. Grischow writes that this happened "circiter 1712 and 1713 nise jam ante." Shortly after that Fahrenheit travelled to Halle and Leipzig, and then Barnsdorf, in conjunction with a colleague named Lange, tried to construct thermometers after the instructions. The scale on these was somewhat different from that on the thermometers which were generally known later as Fahrenheit's, and we read about Barnsdorf that he probably retained "the older or oldest Fahrenheit division." Now from the table it appears that Barnsdorf's thermometers have 7½ at

[4] *Loc. cit.*, p. 271.

[5] Cotte, "Traité de Météorologie," 1774, p. 129.

the freezing point and 22½ at the temperature of the human body, and these larger degrees are again divided into smaller ones, namely, each degree into eight. At all events, this idea of placing 7½ at the freezing point, together with all the other facts that have been mentioned, seems pretty certainly to prove Römer's influence, since it is highly improbable that two persons independently would both think of placing 7½ at the freezing point. Barnsdorf's zero is somewhat higher than that of the later Fahrenheit thermometers.

There is other evidence that Fahrenheit used 7½ at the freezing point and had his original zero a little higher than the later one. In 1737 Prof. Dn. Kirch described[1] a thermometer which he had received from Fahrenheit more than twenty years before. He states there that his thermometer has 7½ at the freezing point, and that his zero lies somewhat higher than that on the later Fahrenheit thermometers.

One more thermometer—perhaps the very oldest—seems based upon a division with fixed points and a scale like Barnsdorf's, although the division, apparently, is quite different. Grischow writes in 1740 that a large thermometer which Fahrenheit had constructed thirty years before for the Royal Society in Berlin, and consequently constructed with the greatest care, still agrees completely with the little thermometers which Fahrenheit had sent a short time before from Amsterdam to Berlin. These small thermometers were graded with the help of two or three fixed points, and are throughout like those we use now. So the first thermometer was also constructed according to fixed principles, for such agreement cannot be due to mere chance; a similar thermometer, which had been used for observations in 1709, and which certainly is one of the first Fahrenheit thermometers constructed, was found in Danzig in 1740.

This thermometer was apparently divided after the manner of the Florentine thermometer: 90 at the temperature of the body, 0 at about summer heat, 90 at the lowest degree of heat (which accordingly corresponded to zero on a Fahrenheit thermometer), and 30 at the freezing point. From the lowest to the highest degree of heat, then, there are $180^\circ = 8 \cdot 22\frac{1}{2}$, from the lowest degree of heat to the freezing point $60^\circ = 8 \cdot 7\frac{1}{2}$, accordingly like Barnsdorf's.

In 1714 Fahrenheit constructed two thermometers for Chr. von Wolf, Chancellor of the University of Halle, who was very enthusiastic about them, and has given a description of them.[2] The scale had 26 degrees; the second degree on the scale was marked "greatest cold," so that from this point to the top of the scale there were 24 degrees; the eighth degree was marked "cold." It reminds us perfectly of a scale which Grischow gives for the older Fahrenheit thermometers with the fixed points 0, 8, 24, which later were changed to 0, 32, 96. So here Fahrenheit hesitated—just as, perhaps, Römer did, according to Horrebow's opinion—and he took 8 instead of 7½. However, taken all in all, there are strong indications that it is Ole Römer's strange number for the freezing point which is the origin of the 32° Fahrenheit now used for this point.

Now, perhaps the objection may be made that if Römer's scale were to be traced in Fahrenheit's, we should find $4 \cdot 60 = 240$ at the boiling point, and not 212; but there is an explanation for this. According to those descriptions of the oldest thermometers which are given above, it appears that the zero in the later thermometers is placed lower than in the earlier ones. Now if the zero in the earlier ones coincided with that of Römer's, the degrees on them must have been shorter than on the later ones, since there must be the same number of degrees within a shorter limit. In the later thermometers the number for the boiling point was found by dividing the space between zero (chiefly determined by means of a cold mixture) and the freezing point into thirty-two equal parts, and marking equal parts off above the freezing point; since these degrees are longer than the older ones, there must be fewer within the same limit, therefore 212, and not 240, at the fixed point, the boiling point.

Kirstine Meyer.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—The Board of Studies in Ethnology will be designated in future the "Board of Studies in Anthropology."

Mrs. Norman-Robinson has offered to found a scholarship in craniology and anthropometry, tenable at University College, in memory of the late Dr. R. C. Benington.

The principal of the University (Dr. H. A. Miers) has been elected chairman of the University Press Committee of the Senate.

In addition to the post-graduate course of lectures at University College, London, by Prof. J. A. Fleming, on "The Theory of the Propagation of Electric Currents in Telegraph and Telephone Cables and in Electric Conductors," two other post-graduate courses have been arranged, namely:—(1) "The Ideal Arch, Metal and Masonry, Theory and Design," by Prof. Karl Pearson; (2) "Steam Turbines," by Messrs. W. J. Goudie and E. G. Izod, both beginning on January 21.

Among the advanced courses of scientific lectures for the coming term arranged in connection with the University we notice the following. The lectures are intended for advanced students of the University and others interested in science, and admission to them will be free. A course of ten lectures on the "Evolutionary Aspects of Palæobotany" will be given by Mr. E. A. Newell Arber at University College, at 4.30 p.m., on dates which are published in the *London University Gazette.* Three lectures on "The Geology and Physiography of Arctic Europe" will be given by Prof. E. J. Garwood at University College on Thursdays, at 5 p.m., beginning on February 24. Dr. W. N. Shaw, F.R.S., will give a course of lectures on "Dynamical Meteorology, with Special Reference to the Forecasting of Weather," at the London School of Economics on Fridays, at 5 p.m., beginning on January 21. A course of eight lectures on "The Rate and Conditions of Chemical Change" will be given in the physiological laboratory of the University by Dr. V. H. Veley, F.R.S., on Fridays, at 5 p.m., beginning on January 21. A course of fourteen lectures on "Protozoan Parasites, with Special Reference to those of Man," will be given at the Lister Institute of Preventive Medicine, Chelsea, by Prof. E. A. Minchin, on Mondays and Thursdays, beginning on January 17, at 5 p.m. A course of three lectures on "The Marsipobranchii," by Mr. F. J. Cole, will be given at University College on Mondays, beginning on January 24, at 5 p.m. A course of three lectures on "Amphioxus," by Prof. E. W. MacBride, F.R.S., will be given at the Imperial College of Science and Technology on Mondays, beginning on February 14, at 5 p.m.

According to the Chicago newspapers, plans are in contemplation for giving the University of Chicago the finest physical laboratory in the United States, if not in the world. It is said that before the building is complete it will have cost 200,000*l.* All the money is to be furnished by Mr. Martin Ryerson, president of the board of trustees of the University, who was also the donor of the present Ryerson Laboratory at Chicago University.

A committee, with Mr. C. P. Trevelyan, M.P., Parliamentary Secretary to the Board of Education, as chairman, and Mr. W. R. Barker, of the Board of Education, as secretary, has been appointed by the President of the Board of Education to inquire into the administration of elementary education endowments. The terms of reference are "to inquire into the administration of (*a*) endowments, the income of which is applicable or is applied to or in connection with elementary education, and (*b*) small educational endowments other than the above in rural areas, the application of which to their proper purposes presents special difficulties; and to consider how far under the existing law it is possible to utilise them to the best advantage; and whether any, and, if so, what, changes in the law are desirable in the direction of conferring upon county and other local authorities some powers in respect of such educational endowments or otherwise."

In an article on "Some Problems of Secondary Education," in the current issue of *The School World,* Mr.

W. A. Brockington, director of education for Leicestershire, raises several questions which deserve the earnest consideration of all who desire a complete and duly correlated national system of education. In the first place, there is the problem connected with the differentiation of secondary schools and the differentiation of the curricula in these schools. Then the question as to how to secure an adequate supply of trained teachers in secondary schools is discussed. "It is of no use," says Mr. Brockington, "to palter with the problem of the training of secondary-school teachers." Thirdly, there is the problem as to the length of the secondary-school life. "Public opinion has still to be educated into the general acceptance of the axiom that secondary education begins at the age of ten or eleven, and must be continued until at least the age of sixteen or seventeen; and that, accordingly, the privilege of free secondary education imposes a real obligation of self-sacrifice upon the parent." Commenting upon what should be the character of secondary education in the future, Mr. Brockington maintains that we should preserve what is good in traditional knowledge, and, keeping our schools in living touch with the changing needs of society, make the curriculum of secondary schools an epitome of the experience of the race. All sorts of teaching, if properly imparted, represent culture—science, theoretical and applied, the construction of engines, and manual work.

SOCIETIES AND ACADEMIES.

DUBLIN.

Royal Dublin Society, December 21, 1909.—Dr. J. M. Purser in the chair.—Prof. W. **Brown**: Permanent steel magnets. With a given quality of steel the dimension-ratio can be found which gives the most effective magnet with a minimum weight of material. Also the results of six months' tests of fourteen different steels show that magnets made of chrome and tungsten steels are the most permanent.—Major F. **Eassie**: Some variations in the skeleton of the domestic horse and their significance. The author states that in whole races of the domestic horse the skeleton gives proof of deterioration from the type of the wild species, and that to a great extent this deterioration exists in horses in every country, and that it is easily recognisable in the living animal. It is due originally to unsuitable environment and breeding from deteriorated stock. As the result of observations of a large series of horses of different races, the author found three main variations in the skeleton, viz. in the relative length of the segments of the head and spine, of the arm, and of the thigh. That the short spine is a primitive character he considers proved by the remains of horses found in recent formations in the valley of the Nerbudda. In the evolution of the horse from its remotest ancestors in the Lower Eocene the arm and the thigh have gradually been shortened, and this shortening has determined its speed. The author also suggests that the short spine, arm, and thigh, respectively, were dominant characters as regards heredity, and that deterioration from the type of the wild species was probably recessive.

PARIS.

Academy of Sciences, December 27.—M. Bouchard in the chair.—The president announced the death of M. Bouquet de la Grye, past-president of the academy, and of M. Lortet.—Emile **Picard**: A class of developments in series of fundamental functions connected with certain functional equations.—M. **de Forcrand**: The hydrates of rubidium and cæsium. Particulars are given of the isolation of $RbOH+H_2O$, $RbOH+2H_2O$, $CsOH+H_2O$. The melting points of these compounds and heats of solution are given.—R. Jarry **Desloges**: The gradual retreat of the southern polar cap of Mars. A reproduction is given of sixteen photographs of the polar cap of Mars at dates between June 23 and October 19.—M. **Coggia**: Observations of comets made at the Observatory of Marseilles with the Eichens 26-cm. equatorial. Data are given for Daniel's and Halley's comets on December 11 and 16.—M. **Borrelly**: Observations of Daniel's comet, 1909*e*, made at the Observatory of Marseilles with the 16-cm. finder. Data given for December 9, 10, and 11. The comet is round, with a nucleus placed eccentrically.—P. **Chofardet**: Observations of the new Daniel's comet, 1909*e*, made at the Observatory of Besançon with the bent equatorial. Data given for December 14, 16, and 18. Comet appeared as a round nebulosity, 30″ to 40″ diameter, with a slight condensation at its centre. Brightness, as a whole, about the twelfth magnitude.—MM. **Montangerand** and **Rossard**: Observations of Halley's comet made at the Observatory of Toulouse with the Brunner-Henry equatorial. Data given for December 4, 8, 14, and 16.—J. **Haag**: Families of Lamé composed of surfaces admitting a plane of variable symmetry.—D. **Pompéiu**: The representation of analytical functions by definite integrals.—Charles **Reignier**: The calculation of the fly-wheels of rolling mills.—L. **Lecornu**: The fly-wheel of motors for flying machines.—E. **Jouguet**: The velocity of waves of shock and of combustion.—Jean **Becquerel**: The influence of a magnetic field on the damping of light vibrations. A discussion of the absorption bands produced in a magnetic field by xenotime and tysonite at the temperature of liquid (−253° C.) and solid hydrogen (−259° C.).—V. **Bournay**: The adsorption of ions.—L. **Houllevigue**: The preparation of thin films by volatilisation in a vacuum. A platinum wire is coated with a layer of the metal to be deposited, and heated to the necessary temperature in a high vacuum. The film is formed on a glass plate kept in rotation near the hot wire. The method has been successfully applied to the production of thin films of platinum, gold, silver, iron, copper, cadmium, zinc, and tin.—G. A. **Hemsalech** and C. **de Watteville**: The yellow, orange, and red regions of the high-temperature flame spectrum of calcium. Measurements are given for the calcium lines produced in the oxy-acetylene flame; it is shown that the spectrum is very similar to that observed by King in the electric furnace at a temperature of about 2800° C.—E. **Briner** and A. **Wroczynski**: Chemical reactions in gases submitted to very high pressures. The decomposition of nitric oxide and the formation of nitrosyl chloride. Pure NO at pressures greater than 250 atmospheres is decomposed into N_2O_3 and N_2. This corresponds to the observed production of nitrosyl chloride by the compression of a mixture of nitric oxide and hydrochloric acid.—L. **Brüninghaus**: The law of maximum phosphorescence: an attempt at a theory.—R. **Boulouch**: A demonstration of the phase rule. A reply to remarks by M. Müller on the same subject.—H. **Baubigny**: The necessity for the exact study of reactions. Reply to a criticism of M. Colson.—Em. **Vigouroux**: The alloys of nickel and copper. A study of the electromotive forces of these alloys does not point to the existence of any definite compounds of these two elements.—Em. **Pozzi-Escot**: The estimation of nitric nitrogen by reduction with amalgamated aluminium. It is claimed for the process described that it possesses advantages both in speed and accuracy over those commonly employed.—Georges **Dupont**: The stereochemical isomerides of hexine-3-diol 2·5, $CH_3.CH(OH).C{\equiv}C{-}CH(OH){-}CH_3$. The two isomers were separated by means of the properties of the dibromides.—M. **Danaila**: The synthesis of 5 : 7 : 5′ : 7′-tetrabromo-indigo and 5 : 7 : 5′ : 7′-tetrachloro-indigo.—Gabriel **Bertrand** and M. **Holderer**: Bellase and the diastatic splitting up of cellose.—L. **Cayeux**: The mineralogical evolution of the primary oolitic iron minerals of France.—J. **Dumont**: The chemical decomposition of rocks. Rocks of different types were submitted to the action of pure water, carbonic acid, dilute hydrochloric acid, and solution of calcium chloride. The rocks were slowly attacked in all these solutions, the amount of material finally coming into solution being very small, and depending upon the state of division of the rock.—Em. **Perrot** and M. **Leprince**: *Adenium Hongkel*, the ordeal poison of the French Soudan. This plant is called *Kidi-Saramé* by the natives. From the aqueous alcoholic extract of the flowers a highly toxic active principle was isolated of the constitution $C_{20}H_{31}O_8$. It was definitely proved to be neither an alkaloid nor a glucoside, and its true nature still remains undetermined.—J. E. **Abelous** and E. **Bardier**: The general physiological effects of urohypotensine. Experimental studies on rabbits and dogs.—A. **Contamin**: The X-rays and cancerous mice. The action of the X-rays is more efficacious when the tissue of the tumour is young; the resorption of a large tumour causes the death of the animal, probably by poisoning.—Cl. **Regaud** and Th. **Nogier**: The complete and definitive sterilisation of the testicles of the rat, without any lesion of the skin, by a single application of X-rays filtered through aluminium.—Fred **Vlès**: The value of muscular striæ from the spectrographic point of view.—Jules **Auclair** and Paul **Braun**: Two cases of Maltese fever probably contracted at Paris. Both cases, which were definitely proved to be true Maltese fever, were probably contracted from handling sheep skins.—M. **Ledentu**: Vascular tumours and aneurisms of the bones.—P. **Bonnier**: The bulbar centres and intestinal diaphylaxy.—B. **Collin**: Some remarks on two new species, *Dendrosomides paguri* and *Podophrya fixa*.—Gabriel **Arthaud**: The salivary spirochætes.—J. **Savornin**: The palæogeographical evolution of Cape Bon and the direction of the folds of the Atlas, considered as the result of two orthogonal orogenic actions.—Em. **de Martonne**: The unequal distribution of glacial erosion in the bed of Alpine glaciers.—E. **Noël**: Tunisian hydrogeology.—Henryk **Arctowski**: The dynamics of climatic variations.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii., for 1909, contains the following memoirs communicated to the society:—

July 17.—H. **Bohr**: The summability of Dirichlet series.—D. **Hilbert**: The theory of conformal representation.—D. **Hilbert**: The form of a surface of the fourth order.

July 31.—A. **Coehn** and U. **Raydt**: The quantitative validity of the law of distribution of charge between dielectrics in contact.—C. **Runge**: The determination of position in balloons.—P. **Koebe**: The uniformisation of given analytic curves (iv.).

DIARY OF SOCIETIES.

THURSDAY, JANUARY 6.

RÖNTGEN SOCIETY, at 8.15.—(1) A Comparison between the Skotographic and Electroscopic Effects of certain Animal Substances with the same Effects of Uranium, Thorium, &c.; (2) Retardation of Electroscopic Leak by Means of Recognised Radio-active and other Substances; (3) Masked Radio-activity; (4) Influence of Radio-active and certain other Substances upon the Division of Animal Cells: Dr. W. S. Lazarus-Barlow.

FRIDAY, JANUARY 7.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Application of the Pitot Tube to the Testing of Impulse Water-wheels: W. R. Eckart.—An Account of a Visit to the Power Plant of the Ontario Power Co. at Niagara Falls: C. W. Jordan.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Oil Fuel: D. S. Richardson.

MONDAY, JANUARY 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Travels of a Naturalist in South-west Africa: Prof. H. H. W. Pearson.

VICTORIA INSTITUTE, at 4.30.—Modern Conceptions of the Universe: G. F. C. Searle, F.R.S.

TUESDAY, JANUARY 11.

ILLUMINATING ENGINEERING SOCIETY, at 8.—Glare, its Causes and Effects: Dr. J. H. Parsons.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Design of Rolling Stock for Smooth-rail Working on Heavy Gradients: F. W. Bach.

WEDNESDAY, JANUARY 12.

GEOLOGICAL SOCIETY, at 8.—The Igneous and Associated Sedimentary Rocks of the Glensaul District (County Galway): C. I. Gardiner and Prof. S. H. Reynolds. With Palæontological Notes by F. R. C. Reed.—The Gneisses and Altered Dacites of the Dandenong District (Victoria), and their Relations to the Dacites and to the Grano-Diorites of the Area: Prof. E. W. Skeats.—Recent Improvements in Rock-section Cutting Apparatus: H. J. Grayson.

THURSDAY, JANUARY 13.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On the Atomic Weight of Strontium: Sir Edward Thorpe, C.B., F.R.S., and A. G. Francis.—On the Approximate Arithmetical Solution by Finite Differences of Physical Problems involving Differential Equations, with an Application to the Stresses in a Masonry Dam: L. F. Richardson.—On a Method of Determining the Viscosity of Gases, especially those available only in Small Quantities: A. O. Rankine.—Recombination of Ions at Different Temperatures: P. Phillips.—On the Electricity of Rain and Snow: Dr. G. C. Simpson.—On the Polarisation of X-Rays compared with their Power of Exciting High Velocity Kathode Rays: L. Vegard.

MATHEMATICAL SOCIETY, at 5.30.—The Transformations of Coordinates which can be used to transform One Physical Problem into Another: H. Bateman.—On Homogeneous Oscillation: Dr. W. H. Young.—On the Determination of a Semi-continuous Function from a Countable Set of Values: Dr. W. H. and Mrs. Young.—Note on a Former Paper on the Theory of Divergent Series: G. H. Hardy.—On the Expression of a Certain Function by Means of a Series of Polynomials: Dr. H. F. Baker.—On the Double Sixers of a Cubic Surface: Dr. H. F. Baker.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Lord Kelvin's Work in Telegraphy and Navigation (*Second Kelvin Lecture*): Prof. J. A. Ewing, C.B., F.R.S.

FRIDAY, JANUARY 14.

MALACOLOGICAL SOCIETY, at 8.—Note on *Helix desertorum*: Mrs. G. B. Longstaff.—Description of *Thersites* (*Glyptorhagada*) *Hillieri*, n.sp., from Central South Australia: E. A. Smith.—Note on *Athoracophorus Schauinslandi*: Henry Suter.—The Ampullaridæ of the Eastern Hemisphere. Description of New Species of Donovania, Scutellina, Fissurella, and Pisania: G. B. Sowerby.—Marine Mollusca from the Kermadec Islands. Notes on Polyplacophora, chiefly Australasian: T. E. Iredale.—Helicoids from New Guinea and Description of a New Species of Papuina: G. K. Gude.

THURSDAY, JANUARY 13, 1910.

A JAPANESE PRIEST IN TIBET.

Three Years in Tibet. By The Shramana Ekai Kawaguchi. Pp. xv+719. (Adyar [Madras], Benares and London: Theosophical Publishing Society, 1909.) Price 16*s.* net.

A NEW book on Tibet, offered to "the English-knowing public" by a Japanese priest who acted for a time as physician to the Grand Lama, raises our expectations of finding therein some fresh and interesting views of Tibetan life as seen from the inside. For the author enjoyed the advantage of moving freely behind the scenes, in the palace and in the monastic temples, in intimate relations with the "Living Buddha," and with many of the notabilities of this Old-World State, at a time when it was pursuing the even tenour of its existence, undisturbed by war's alarms.

A perusal of the volume, however, even in this respect, is somewhat disappointing to a European reader. It is a shallow, rambling, and whimsical narrative, from the standpoint of an emotional oriental monk, upon his wanderings on a pilgrimage from shrine to shrine in a land which he knew little about, and over ground mostly described in detail by European writers. Of geographical or scientific data there is positively nothing of any value, and little that is new even in regard to the religion of the country. Nevertheless, the reader who patiently perseveres through much that is trivial and tiresome may pick up some grains of information respecting the life in the great lamaseries.

The personality of the writer himself is quaintly romantic at times. On starting from Japan for Tibet in 1897, on what he tells us was a search for Sanskrit Buddhist books—a search in which he proved wholly unsuccessful—Mr. Kawaguchi, in his Buddhistic zeal, extracted from his friends, as farewell presents, their pledges to abstain from stimulants or tobacco-smoking and from "the brutal business" of catching fish. "About forty persons willingly granted (this) my appeal."

His æsthetic Japanese instinct leads him to break out frequently into a rhapsody or "*uta*" at the sight of some picturesque scene or aspect of nature; though at times he regretfully tells us that "I wished to embody my sentiments in a few verses, but the inspiration would not come." In "the *Dalai* jungle," which is the nearest he can get to the Himalayan "Tarai," where he halted on the way through Nepal to the Tibetan frontier, he heard a tiger roar, on which "an *uta* came to me:—

"The night sleeps still and calm, the moon shines bright,
What ho!—so loud a roar the stillness breaks,
Vibrating—ah! it is a tiger fierce! In ripples rough his roar terrific throws
The surface even of the mountain stream."

The cuckoo's cry for him, instead of being a pleasure, was "awful."

"My sense of loneliness was heightened by the note of the cuckoo, who now and then broke the oppressive silence and an *uta* then came to me thus:—

"In tortuous paths my lonely way now lies
Among rough mountain tracks and scenes all
The rocks and giant trees in silence stood wild
With naught to break the silent depths around
Except the solitary cuckoo's notes
That make the awful silence more profound."

A flock of cranes leads him to fire off the following:—

"Like feathers white the snows fall down and lie
There on the mountain-river's sandy banks;
Ko-Kow, Ko-wow! sounds strange, a melody
I hear—I search around for this strange cry.
In majesty these mountain cranes
I find are proudly strutting—singing thus."

His visionary temperament, indeed, fired by a generous credulity, causes him often to fail in distinguishing fancies from facts. At Sna he heard the voice of a supernatural being calling to him, and again at Sera monastery; and he elsewhere tells us "I was still in an extatic (*sic*) mood." This must have been his mood also when he saw Lhasa and Potala from the track over the "Genpa" (properly Khampa) pass of the Yamdok, the one followed by the Mission, and whence both Lhasa and Potala were certainly invisible. Facts, indeed, are weak points with him throughout. To begin with, even his very first word in the title of his book, "*Three* Years in Tibet" (on the strength of which he absurdly claims for himself a position of greater authority on Tibetan matters than Csoma and Jaeschke, whereas his book shows him to be utterly lacking in scholarship, and even in ordinary knowledge of the language), is falsified by his own proof. On p. 76 he tells us that he crossed the Tibetan frontier for the first time on July 4, 1900; and on pp. 641 and 650 that he finally re-crossed it on emerging from Chumbi on June 14, 1902, thus giving the duration of his entire stay in Tibet as only *one year and* 345 *days* instead of the "*three* years" to which he gratuitously lays claim! This sort of thing is typical of his matter throughout, so that he is not to be taken too seriously. Nor does he allow his ignorance of details to stand in the way of providing precise fictitious ones. He carried no map or any instruments with him, save a small compass registering the cardinal points, yet he devotes a chapter with the heading "22,650 feet above the sea-level" to a description of his sensations in a snowstorm, when he was somewhere on the plateau, he did not know where. It will be news to the Mission force and to the hundreds of men of the convoys who drank the water of the Yamdok Lake at Nagartse, &c., for several months to be told that the water "is poisonous."

He travelled in the guise of a Chinese Buddhist priest, which his Mongoloid face and acquaintance with the Chinese language rendered not difficult for him. What was more important, he posed as a physician, and, endowed with unbounded assurance and luck, acquired such fame by his "cures" that this brought him to the favourable notice of the Grand Lama. "I came to be regarded as a god of medicine," he says, though he naïvely confesses in excuse for his charlatanism that, not having had any regular medical training, "*I know I made a very dangerous doctor, but I was obliged to go on as a pedant domineering over a society of ignoramuses*"—this is very fine, and worthy of being preserved! Fortunately for Mr. Kawaguchi, the Dalai Lama himself became one of those ignoramuses, and conferred on the "doctor" his intimacy and confidence. But Mr. Kawaguchi is strangely silent as to the subjects of those interesting conversations, beyond the bold general statement that

> "I heard and saw much of him (the Grand Lama) and had frequent interviews with him. I judge that he is richer in thoughts political than religious. He seems to fear the British most, and is always thinking how to keep them from Tibet."

Living in constant terror of being robbed explains, perhaps, the low opinion our traveller has formed of his Tibetan co-religionists—so widely different from the experience of sympathetic Western travellers like Rockhill and others. He says:—

> "It is impossible to trust oneself entirely to Tibetans, for honesty is observed only among people who are known to one another, and only so long as actions are done before the public gaze. Social restraints are no sooner removed than the Tibetan is ready for any crime or enormity" (!).

Our pious priest, therefore, was perpetually inventing falsehoods to deceive his interlocutors, and to "lay false scents," as he terms it.

When the secret of his disguise leaked out, that he was not a Chinaman, but a Japanese, he tells us that he made a "bolt" from Lhasa to India, assisted by an "ex-Minister and his nun-wife (*sic*)." As there was no pursuit, however, his excitement on the way was perhaps more imaginary than warranted. Certainly we cannot say that he has brought back to us any information which is new or important.

The get-up of the book is not at all creditable. It is in the poorest Indian style—it was printed in Madras, and looks it. Misprints also abound, and there is no index. The illustrations have been roughly drawn by a draughtsman in Japan in conventional Japanese style, and exhibit little that is characteristic of Tibet.

We leave the book with the feeling that the really interesting things have been left out.

L. A. WADDELL.

CRITICISM IN GEOLOGY.

La Géologie générale. By Prof. Stanislas Meunier. Pp. xii+344. Second edition. (Paris: Félix Alcan, 1909.) Price 6 francs.

Evolution géologique de la Terre et ancienneté de l'Homme. By Alphonse Cels. Pp. viii+248. (Brussels: Lebègue et Cie., 1909.) Price 5 francs.

THE one point common to these two treatises is that both authors look with a certain enthusiasm on the earth as an active living whole. Prof. Meunier claims that his originality consists in this. For forty years he has worked towards the expression of a theory of the earth, in which the guiding idea is that

> "Le globe est un véritable organisme, où des appareils harmonieusement associés poursuivent la réalisation de fonctions dont l'ensemble se traduit par les progrès d'une évolution planétaire sans arrêt."

The rocks of the earth's crust are in a state of continuous transformation; the characters of a stratum belong to all the ages that have passed since the time of its deposition.

To the mind of the geologist in these islands there is nothing very new in the propositions so clearly set forth in the author's "avertissement," and developed in the work. Some of them, such as the mode of production of flint in limestone (p. 104), and the part played by rain in the excavation of valleys (p. 162), deserve emphasising in lecture-rooms where other views may have prevailed. But they seem rather home-truths nowadays, and are, unfortunately, associated in the book with much that has been discarded in the face of cumulative evidence, and with much that must be characterised as exaggeration of a special point of view. Prof. Meunier, for instance, seems to regard oolitic structure as essentially of secondary origin in the rocks in which it occurs (p. 120); he denies, somewhat late in the day, the glacial origin of the Dwyka conglomerate and similar contemporaneous deposits (p. 277); and, while urging that springs and waterfalls tend inevitably to recede, he minimises the excavating action of a river throughout its ordinary course. Even where we are all prepared to follow him, his triumphal progress is accompanied by too much slaying of the slain. Yet here, as in his previous works, his comments on current explanations of phenomena are always well worth reading. The appearance of a river in a valley as the result of the excavation of the floor down to the surface of the permanent water-table is not new to students of English "bournes"; but it gives one food for thought when applied to larger and permanent cases.

The production of a volcano (p. 74) by the faulting up of a hot region over one saturated with water is distinctly fascinating. The essay (pp. 96–103) on "alluvions verticales," including the South African diamond pipes, has novelty, at any rate, in its treatment of the subject. The essay by Montlosier on the erosion of volcanic relics in Auvergne, published in 1788, was well worthy of resuscitation (p. 158), and forms an interesting feature of a chapter in which full justice is also done to Poulett Scrope. Prof. Meunier has always maintained the community of origin of volcanic and plutonic igneous rocks of various ages; but we doubt if the diagram on p. 82 will gratify students of differentiation. Mr. R. A. Daly, to whom igneous rocks are all basic to begin with, will regard it almost with dismay.

Prof. Meunier's remarks on the relics of the latest—and to him the only—ice-age have a Lyellian ring, but will not satisfy the growing school of glacial investigators. While he rightly urges that considerable areas remained free from ice, though others became for a time concealed, he can hardly convince us nowadays that the glacial epoch was a local phenomenon, shifting from place to place under changes of geographical conditions. Twenty years ago many of us may have said the same, particularly if we lived where glacial relics were not abundant. Travel and conference with others have wrought a great change in this respect, and we may venture to think that Prof. Meunier still prefers to remain a critic rather than a field-observer. His volume is a pleasure to read, for he has the happy manner of an essayist; but it is full of pitfalls for the beginner. It contains, moreover, too many misprints, and is not provided with an index.

M. Cels, fortified in his geology by long and numerous quotations from De Launay's "La Science géologique," rejoices as a giant to run his course. He reminds us at all points of the sailor who, hearing for the first time of an essential fact of sacred history, left the meeting-house and knocked down an unoffending Jew. M. Cels has discovered the Huttonian doctrine; for him, as for Prof. Meunier, the world lives and is subject to evolution (p. 29); but he looks in vain (p. 247) for the traces of a beginning or of an end. Consequently, in the light of this great truth, all geologists, and notably the late M. de Lapparent, seem to him but as blind guides. Lamarck and Darwin (p. 39) have deceived enthusiastic men of science by presuming a beginning of life, from which our existing organic structures spread.

The author's devotion to causes now in action (p. 46) is that of a convert won by faith. With the earlier and not the later Lyell, he would lay enormous stress on the imperfection of the record, and would trace man back beyond the "eoliths" of early Eocene times (pp. 202 and 219). With the early Huxley, he would urge that strata containing the same fossil types in different parts of the globe may be separated by great intervals, even of geological time; and he further believes that the similarity of faunas is due to similarity of conditions of environment rather than to any contemporaneity in time. Prof. Meunier dislikes the idea of a general glacial epoch, on the ground that the earth's climates have got steadily colder; how then, he asks, shall we account for the disappearance of an epoch colder than that in which we now live? M. Cels dislikes it because he believes in the shifting of our polar axis (p. 107) and in the sufficiency of this vital earth to manage all its own affairs. Yet it is interesting to find Prof. Meunier employing the same arguments for demolishing the glacial epoch (p. 274 of his work) as M. Cels employs against the idea of successive geological periods marked by faunas in course of evolution.

M. Cels, during his recent reading, has discovered many valuable things, such as the occurrence of true sediments among archæan masses, and the difficulty of finding any relics of the primordial crust—facts pointed out long ago by Sir A. Geikie, but which are here dated back only to 1905. His studies among the modernists throw him, however, more and more towards Hutton, and even towards Pythagoras (p. 232), and his hope is to reform geology altogether. Both these books are out of the common; but neither is quite so stimulating as Reyer's "Prinzipienfragen," which was reviewed in these columns in 1908.

GRENVILLE A. J. COLE.

CHEMICAL PHILOSOPHY.

The Fundamental Principles of Chemistry. An Introduction to all Text-books of Chemistry. By Prof. W. Ostwald. Authorised translation by Harry W. Morse. Pp. xii+349. (London: Longmans, Green and Co., 1909.) Price 7*s.* 6*d.* net.

SINCE the retirement of Prof. Ostwald from the directorship of the Institute of Physical Chemistry in Leipzig, his literary activity appears to have increased, although for many years his output has been phenomenally great. With his departure from the atmosphere of the laboratory, from the sphere of attraction of experimental problems, the philosophic, pedagogic and historical aspects of chemical science have claimed his attention more closely than was possible heretofore.

The present work is essentially philosophical in character. In a sense it is an attempt to work out a system of chemistry without reference to the properties of individual substances, and its chief characteristic consists in a minute analysis of various chemical conceptions, and of the facts of experience from which they are derived.

The range of analysis is indicated by the titles of the separate sections:—Bodies, substances and properties; the three states; mixtures, solutions, and pure substances; change of state and equilibrium; solutions; elements and compounds; the law of combining weights; colligative properties; reaction velocity and equilibrium; isomerism; and, finally, the ions.

At the outset the author takes the view that the conception of matter is unnecessary, and this term is not made use of in the text. The idea that matter is something originally existing, something which is at the basis of all phenomena, and in a sense independent of them, is very widely spread, and any attempt to get rid of the conception will have to show a clear gain in simplicity, so far as derived concepts are concerned, before chemists agree to discard this particular conception. Such gain is not demonstrated, and the author's assertion that matter can be shown to be made up of the simpler concepts weight, mass and volume will doubtless be objected to on the ground that weight is not a conception of a simpler order than matter.

About half the book is taken up by the chapters on solutions and elements and compounds. A good deal seems to be made of the fact that pure substances can be regarded as limiting cases of solutions. Two component systems are subjected to a somewhat laborious analysis, and numerous diagrams are given to illustrate the various types of possible phase combinations. Chief interest attaches, however, to the demonstration that there are two component mixtures and solutions—viz. those which admit of hylotropic transformation—which behave exactly like pure substances in respect of such change. These solutions can, however, be readily differentiated from pure substances, for the hylotropy of the former is limited to certain definite temperatures and pressures, whereas that of the latter extends over considerable ranges of these variables.

The relationships involved in hylotropy are made the basis of the author's conception of the elements, an element being a substance which cannot be transformed into another non-hylotropic substance within the entire range of attainable energy influences. By energy influences are understood any processes carried out without the actual addition of other substances. This statement is, however, scarcely adequate for the sifting out of the chemical elements. It may have been the case before the discovery of the radio-active substances, but the spontaneous disintegration of these obviously represents a non-hylotropic change, and as a consequence these elements do not fall into line.

The discussion of the laws of chemical combination, of colligative properties, and of catalysers is clear and lucid, but does not present any striking novelty.

In the chapter on ions the nature of a salt is examined. To the many definitions of this particular type of chemical individual which have been given, the author adds a new one. According to Ostwald, a salt is a substance which has the properties of a pure substance in the undissolved condition, whilst it exhibits the properties of two different substances when in solution. If in all solvents all salts are ionised or dissociated, this definition is probably sufficient to describe this group of bodies. It is, however, doubtful whether any practical test, based on the definition, could be actually applied to determine whether any particular substance is a salt or not.

In spite of the fact that we may not agree with the author's choice of fundamental concepts, and that certain results to which he is led are not in accordance with actual facts, it cannot be denied that the general treatment of the subject is profoundly interesting, and that the analysis of facts and ideas is conducted with great ingenuity. The subtitle cannot be taken very seriously, for it is too much to expect that the contents of the book can be digested by the future chemist prior to his study of the orthodox text-book. It should, however, appeal to the more mature student, to whom it is confidently recommended.

H. M. D.

OCEANOGRAPHY IN THE NORTH ATLANTIC.

Scientific and Biological Researches in the North Atlantic, conducted by the Author on his Yachts "The Walwin" and "The Silver Belle." By Dr. R. Norris Wolfenden. Pp. vii+234. (London: Rebman, Ltd., 1909.) Price 7s. 6d. net.

IN this work Dr. Wolfenden gives an account of the hydrographic and biological researches carried out on board his yachts, the *Walwin* and *Silver Belle*, from 1899 to 1907. The investigations, begun in the Færöe Channel with the *Walwin* (36 tons), which was replaced in 1902 by the *Silver Belle* (130 tons), were afterwards extended to the Azores and Gibraltar.

Apart from the observations actually recorded, this account is valuable as showing what a large amount of useful scientific work may be carried out on board a sailing yacht of moderate size, the cost of the additional gear necessary being only a small proportion of the original outlay. It will probably be a surprise to many to learn that from a sailing yacht of 130 tons soundings, physical observations, and tow-nettings may be taken at a depth of 1500 fathoms with comparative ease and certainty.

The first sixty pages are occupied by a summary of the various cruises, and give some idea of the inclement weather which may be expected in the North Atlantic even in summer. The work was carried on in spite of considerable difficulties and hardships, and the amount accomplished is very much to the credit of the *Silver Belle* and her crew of Shetlanders. An accompanying chart shows the positions of the stations on each cruise, and also the contour lines of depth of 100 and 2000 fathoms. The 100-fathom line is, however, erroneously drawn outside the Porcupine Bank, off the west coast of Ireland, instead of passing between it and the mainland.

Following the narrative of the cruises, Dr. Wolfenden gives the benefit of his lengthy and somewhat costly experience in the choice and manipulation of fishing engines and physical apparatus. It appears that the taking of water samples and temperatures in deep water can be worked for the most part without mishap even in rough weather, but that a heavy sea prevents the satisfactory use of closing plankton nets. The chief source of danger is the rolling of the ship, which, by slackening the wire, causes it to "kink," and thus prevents the descent of the opening and closing messengers, if it does not result in the loss of both wire and net.

The greater part of the book is occupied by an account, by Dr. H. N. Dickson, of the hydrography of the various cruises. Except in the case of the Færöe Channel, which is dealt with in considerable detail, Dr. Dickson contents himself with pointing out the general conditions of salinity and temperature prevailing over the regions investigated, deferring the further discussion of the results until a longer series of observations has been accumulated. He directs attention, however, to the effect of the highly saline water of the Mediterranean flowing outwards through the Straits of Gibraltar. The section plotted on p. 161 shows clearly how the denser water, pouring over the sill as if over the edge of a waterfall, sinks to a depth of about 600 fathoms, and at that level streams out horizontally in a layer more saline than that above or below it. The influence of this water was noticeable in the high salinities at intermediate depths found off the coast of Portugal in 1904 and 1905, and it will be interesting to learn, when the results are published, whether the plankton taken on these occasions contains any indication of a Mediterranean origin. Dr. Dickson alludes to the probability of this water reaching the English Channel, and emphasises the importance of continued observation. Other points of interest dealt with are the differences of salinity and temperature on the north and south sides of the Porcupine bank, and the accumulation of evidence to show the existence of a cold bottom current flowing southwards over the Wyville-Thomson ridge. A complete series of sections and full tables of the salinities, temperatures, and meteorological observations on each station are given, but a serious omission is the absence from the tables of a column for the depth of water, which can only be ascertained by reference to the narrative of the cruises.

The last forty pages contain an instalment of the biological work accomplished on the cruises. The subjects treated are:—Fishes, by Mr. E. W. L. Holt and Mr. L. W. Byrne; Amphipods and Isopods, with descriptions of two new species, by Mr. W. M. Tattersall; and *Pyrosoma spinosum*, by Mr. G. P. Farran.

The printing, illustrations, and get-up of the book are excellent, and a few misprints and obscurities, chiefly in the earlier pages, do not seriously detract from the value of Dr. Wolfenden's contribution to oceanography. It is to be hoped that we soon may have a second volume dealing further with the large amount of biological material which must have been amassed.

THE CASE FOR EUGENICS.

The Family and the Nation: a Study in Natural Inheritance and Social Responsibility. By W. C. Dampier Whetham, F.R.S., and Catherine Durning Whetham. Pp. viii+233. (London: Longmans, Green and Co., 1909.) Price 7*s.* 6*d.* net.

"THE power of heredity," writes Mr. Whetham, "is an old story; 'family likeness,' 'family characteristics,' 'family temper,' are expressions which convey ideas well known to all men. Yet with amazing inconsistency we have taken little if any account of such knowledge in our conduct, little if any in our theories of social and political life. We have talked and acted as though it were of no account how men were bred, or what classes of the community were reproducing themselves fastest and what declining in number, as long as each individual was enabled by improved conditions to pass his brief lifetime in increased comfort and security."

It is the duty of preachers of eugenics, a duty conscientiously undertaken by the author, to end this state of affairs; to teach our future statesmen what biological factors govern the rise and fall of nations, and to educate public opinion in such a way that, aided by the legislation that will then be possible, it will insist on the more rapid multiplication of the desirable components in our society, and aim at the elimination of the rotten parts which now permeate it. Mr. Whetham's book cannot fail to influence all who read it. He writes with the clearness and vigour which flow from conviction based on clear thinking; and thus, having the facts with him, presents a strong case strongly.

The line of argument adopted is as follows. First, the importance of heredity is insisted on, and the methods by which it is being studied scientifically are described, namely, the analytical method initiated by Mendel and developed by Prof. Bateson and others, and the statistical method originated by Sir Francis Galton and extended by Prof. Karl Pearson.

Many pedigrees are given as instances of inheritance in man, and are illustrated by diagrams like those published in the "Treasury of Human Inheritance," now being produced by the Galton Laboratory. The important question of the relative influence of heredity and environment is referred to, but since there is very little evidence available for discussion, it necessarily receives but scanty treatment. As the author points out, the only quantitative study of the subject yet published is the work of Barrington and Pearson on keenness of vision and defects of eyesight. They found that no measurable relation exists between powers of vision and environment, whereas the influence of heredity is well marked.

Two chapters follow, the one on the inheritance of mental defect, and the other on the inheritance of ability, the latter being based largely on Sir Francis Galton's "Hereditary Genius." The influence of heredity is further shown in an examination of the circumstances causing the rise, fall, or extinction of families, and finally the effect of heredity acting in conjunction with a differential birth-rate is treated very fully.

It is a well-known fact that the birth-rate in Great Britain fell from 36 per 1000 in 1876 to 27 per 1000 in 1907. This in itself may give cause for alarm, but the most serious feature of the fall is that it has not been the same in all classes. If the lowest stratum of society had been affected equally with the higher strata, the 27 per 1000 would have been reduced to a much lower figure. As it is, the lowest stratum is as prolific as before, therefore our birth-rate has become selective. The least valuable portions of the population are selected to contribute a disproportionately large share of the next generation, by the action of the more valuable portions in bringing about at any rate a partial self-elimination.

The author gives historical instances, in which the action of a selective birth-rate produced by various causes has influenced the rise and fall of nations. As an example we may quote the influence of the Dominican and Franciscan monks, of whom the former came to England in 1220, the latter in 1224. Through their preaching and persuasion, the majority of our men of intellect were drawn into the monasteries and thus rendered sterile. Roger Bacon, Adam Marsh, Robert Grosseteste, Dun Scotus, and Occham are but a few names from a host of others. As a result came the stagnation of the fourteenth and fifteenth centuries, which was only ended by the overthrow of the monasteries in the time of Henry VIII. Then followed the "glories of the Elizabethan age," and "a period of scientific and literary activity, which carried England on through the seventeenth century."

In conclusion, we may heartily recommend this book to those who are interested in the study of heredity as affecting human societies. It is no disparagement to say that the arguments used have many points in common with the teaching of Prof. Karl Pearson. To him, as well as to Sir Francis Galton, all those who write on eugenics must owe a debt. E. H. J. S.

INDIAN WOODS AND THEIR USES.

Indian Woods and their Uses. By R. S. Troup. Pp. 273+ccxviii. (Calcutta: Government Printing Office, 1909.) Price 4*s.*

THIS work is the outcome of a gradual development of research on the part of the Indian Forest Department. The foundation of the system now instituted was laid in 1883, when Dr. (now

Sir Wm.) Schlich was Inspector General of Forests. He succeeded in obtaining the sanction of the Government of India and of the Secretary of State for India to the establishment of the working-plan branch of the department. Under the regulations then issued, all working plans had to be submitted to the Inspector General, who examined them and communicated his views on them to local governments. The Imperial Superintendent of Working Plans kept a record of the progress of the work by means of annual returns submitted to him by local authorities. In this way, a great store of statistics was collected, which, according to Sir Wm. Schlich's intentions, were to be made available as the work proceeded. Unfortunately, after his departure from India in 1885, little or nothing was done in this respect for about fifteen years.

A fresh move was commenced about the year 1901, when Mr. R. C. Wroughton, then Inspector General of Forests, conceived the idea of the present Forest Research Institute, which was approved by the Government of India. The installation of the institute was, however, carried out by his successor, Mr. J. Eardley Wilmot. It is stationed at Dehra Dun, and consists of six members, namely :—(1) a president, (2) an imperial superintendent of forest working plans, and sylviculturist, (3) a forest zoologist, (4) a forest botanist, (5) a forest economist, and (6) a forest chemist.

Arrangements were made for the publication of (1) Indian forest records, and (2) Indian forest memoirs. The latter are published as quarto volumes measuring 12¼ inches by 10 inches, this being the size used by the Royal Asiatic Society and the Geological Survey of India.

The volume under review is the first number of the economic product series. It is a stately but very unwieldy volume, of 273 pages text, and 218 pages of appendices. It is divided into part i., the various uses of Indian woods according to the different purposes for which wood is used; and part ii., descriptive list of the chief Indian woods.

The indices are two in number, giving (1) the English and trade names, and (2) vernacular names.

As part i. is divided into thirty-four sections, such as agricultural implements, boat and ship building, coopers' work, furniture, mining timber, ordnance work, railway carriages, sleepers, telegraph poles, tools, toys, wood pulp, &c., it follows that many woods are mentioned under a considerable number of sections.

Part ii. deals with each species under a number of heads, such as natural order, synonyms, English name, vernacular names, habitat, description of tree and wood, weight per cubic foot, strength, and chief uses. Under the last head, all that has been said in part i. is here repeated. The list of woods is arranged alphabetically to facilitate reference. The number of species dealt with is 554, or about 10 per cent. of some 5000 woody species, about half of which are trees. The descriptions are based mainly on those in Gamble's "Manual of Indian Timbers," supplemented by the results of a further examination of many species. To ascertain what proportion the latter bear to the former would require a detailed comparison of the two works.

The appendices are no doubt very useful, but they are contained in Gamble's book in far more concise shape, while they are spread over 218 pages in the work under review. Indeed, there is in the latter quite an inexcusable waste of space, which reduces the usefulness of the index of vernacular names considerably; it might have been condensed to one-quarter the space. We believe the work was compiled for the use of firms. If this is so, why was the information, if wanted at all, not brought out in a handy little booklet instead of in this big quarto volume, which requires a table of its own to spread it out upon? For the shape, however, Mr. Troup is not responsible; that was laid down by official orders, which the author would have done well to resist.

The present is the second work published by Mr. Troup, the first being a volume on Indian forest utilisation. Both are, to a considerable extent, compilations. We admire Mr. Troup's remarkable activity, but we hope that his transfer to the post of imperial working-plans officer and sylviculturist will enable him to devote his energy to more fruitful work. The most urgent need is the study of the sylvicultural bearing of the more important Indian timber trees. Gamble's "Manual of Indian Timbers" gives all that is required regarding timbers and their uses, until other branches of forestry have been brought up to the same level.

OUR BOOK SHELF.

A Survey and Record of Woolwich and West Kent. General editors, C. H. Grinling, T. A. Ingram, and the late B. C. Polkinghorne. Pp. viii+526. (Woolwich: Labour Representation Printing Co., Ltd., 1909.) Price 10*s.* 6*d.*

THE publication of this work, originally intended for the Woolwich Congress (1907) of the South-eastern Union of Scientific Societies, has been delayed owing to alterations found desirable in the original scheme, and to the regretted death of one of the editors and the prolonged ill-health of another. As it now appears, it is a valuable contribution to our knowledge of that portion of Kent bounded by the Thames, the Ravensbourne, the Cray, and the outcrop of the chalk between the two last-named rivers. It is, moreover, an excellent example of the beneficial result of cooperation in scientific work, for here we have brought together, in readily accessible form, records of the work of local scientific societies and isolated naturalists. The result, so far as numerical records are concerned, will doubtless be astonishing to many. From a small corner of Kent, only some fifty to sixty square miles in area, a considerable portion within the London postal district, none beyond what might be regarded as the outer suburban zone, a rich flora and fauna are recorded. Of plants there is a list of more than 2000. The number of animal forms is not summarised, but the records, with citations of localities, occupy just over 200 pages; of Coleoptera or beetles no less than 3264 species are enumerated.

The publication of these records will doubtless, as the authors hope, induce others to contribute additions either to the lists of species or of localities, and thus to secure fuller knowledge of the distribution of the organisms. Rapid changes, due to the incursions of man, are taking place within the area, and in a few years' time the records will have an added value in enabling us to trace actual changes, and also, perhaps, some of the causes determining those changes. Almost everyone interested in natural history makes from time to time observations, of minor importance, perhaps, regarded as isolated facts, but valuable if brought together and studied in relation to those of other observers in the neighbourhood. Not the least service rendered by a volume such as this is that it offers a definite place of record for many a fact which would otherwise probably be lost. We have discussed at some length the biological matters, which occupy about four-fifths of the book. In addition, there is a brief general sketch of the geology, in which, as an instance of interrelation between geology and industry, it may be noted that Woolwich Arsenal is said to owe its establishment to the suitability of the local Thanet sands for iron-moulding. Scientific industries and archæology are other interesting chapters, and there is a concluding note on Woolwich as a centre for photography. The geological section has a very useful bibliography, arranged chronologically. The book is well indexed. W. G. F.

The Flora of the Dutch West Indian Islands. Vol. I., *St. Eustatius, Saba, and St. Martin.* By J. Boldingh. Pp. xii+321. (Leyden: late E. J. Brill, Ltd., 1909.) Price 10*s.*

Considering the comparative proximity of the West Indies and the number of nationalities in possession, there is a lack of systematic botanical information in the shape of local floras, so that Mr. Boldingh renders good service by the publication of his work relating to three of the Dutch possessions. It is based primarily on his own observations and collections, together with the collections of his countrymen, Dr. Suringar, Mrs. van Grol-Meyer, and Dr. Lionarons, totalling in all about 5000 numbers. The systematic enumeration comprises 806 species, of which 674 are regarded as indigenous and 166 are confined to the West Indies. The Leguminosæ is the best represented family, with sixty species; the Gramineæ, Compositæ, Polypodiaceæ, and Euphorbiaceæ follow in the order named. Panicum, Polypodium, and Peperomia are the larger genera. Ipomœa supplies nine species, of which two are limited to the West Indies, and another is recorded only for St. Eustatius. Two other endemic species, *Galactia nummularia* and *Calyptranthes Boldinghii,* have only been collected on St. Martin.

The author follows Eggers in the ecological divisions, and distinguishes littoral, cultivated, dry shrubby or Croton, and tree or Eriodendron types of vegetation. The dry shrubby and tree vegetations are well developed on St. Eustatius; on Saba the cultivated regions and certain ferns are notable; St. Martin is characterised by the extent of the littoral and shrubby vegetations, while forests are scanty. Generally speaking, the flora of St. Martin differs from that of the other two islands, and contains a number of plants represented on islands lying to the north, while the proportion stands the other way with regard to certain plants recorded only from islands lying to the south. The author has rounded off his information with geological and meteorological notes, a list of vernacular names, chiefly English, and maps. The flora bears out the general view that there is no striking difference between the plants of neighbouring islands in the group.

Weather Forecasting by Simple Methods. By F. S. Granger. Pp. xii+121. (Nottingham: Henry B. Saxton, 1909.) Price 2*s.* 6*d.* net.

The aim of the author is to provide the means for a single observer "to answer the question 'When will it rain?' in a simple and intelligible manner" without the aid of instruments except a barometer, this, however, being regarded as optional, and not necessary. The methods recommended are based mainly on observations of the size, thickness, extent, height, colours, and forms of clouds. Different aspects of cumulus, cirrus, and stratus cloud are discussed in relation to the weather to be subsequently expected, and isolated examples taken from the author's observations at Nottingham are quoted.

As the result of a long series of observations by an observer who is evidently interested in the subject, the work may prove useful to local observers, but it is doubtful to what extent some of the conclusions arrived at can be considered general. Thus "visibility" is regarded as a sign of good weather, because this phenomenon occurs at Nottingham only during light easterly breezes. In some districts, however, visibility is frequently associated with winds from some westerly point, and is commonly supposed to be a prognostic of rain.

Although Mr. Granger again tells us that meteorology is not an exact but an observational *science,* he says in the same breath that his book is not written on exact and *scientific* lines. He has described it well. His cloud classification is incomplete, and is not that approved by international agreement. He ascribes the formation of cumulus to an electrical cause, and states that lurid red skies in the morning or evening are due to refraction of light. After using the word "gradient" several times he at length defines it as "the slope between two isobars when on one the barometer is one-tenth of an inch higher than the other," and speaks of a gradient of 300 miles, a gradient of 29·9, a shallow gradient, and a form of gradients. There are many other statements which ought to be modified in the light of recent researches. For example, our knowledge of the conditions in the free atmosphere is not as limited as the author suggests, and surely calculation already enters into the science of forecasting, and must continue to do so to an increasing extent.

The arrangement of the work, especially with regard to marshalling the descriptions under some definite plan and arranging them in chapters with appropriate headings, leaves much to be desired. The present arrangement is almost fortuitous.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Invention of the Slide Rule.

I have read with great interest the abstract of the paper on the invention of the slide rule, by Prof. F. Cajori, which appeared in Nature of December 30, 1909. I agree with the author in thinking that the Rev. William Oughtred was the first to suggest that calculations could be made more accurately and rapidly by sliding the edges of logarithmic scales together than by using compasses—the method adopted by Gunter; but Oughtred had a poor opinion of this device, and rightly considered that his circular scale was a great improvement on it. A few years before 1671, Seth Partridge[1] re-discovered the sliding principle, perfected it, and gave an almost complete specification for the slide rule which is used to-day by engineers.

I was fortunate enough recently to come across, in the library of the British Museum, a pamphlet written by Oughtred in reply to an attack make on him by an instrument maker called Delamain. The pamphlet is entitled "To the English Gentrie and all other studious of the Mathematicks, which shall be readers hereof. The just apologie of Wil: Oughtred against the slanderous insimulations of Richard Delamain, in a pamphlet called Grammelogia, or the Mathematicall Ring." The author very forcibly and very successfully rebuts the charges that were made against him. The following gives his opinion on the question of the priority of the discovery of the circles of proportion:—

---

[1] "The Description and Use of an Instrument called the Double Scale of Proportion." (London, 1671.)

"The honour of the invention, next to the Lord of Merchiston,[1] and our Master Briggs, belongeth (if I have not been wrongly informed) to Master Gunter who ex-[illegible] their numbers upon a straight line." He then [illegible]bes the advantages gained by sliding two Gunter's scales together, but points out the defects of this primitive method, and so finally leads up to his circular slide rule.

In the "Epistle Dedicatorie" to Forster's "Circles of Proportion" an answer, said to have been given by Oughtred to a question asking him the reason why he had concealed his inventions so long, is quoted:—

"That the true way of art is not by instruments but by Demonstration; and that it is a preposterous course of vulgar Teachers, to begin with instruments and not with sciences, and so instead of Artists to make their Scholers only doers of tricks, and as it were Juglers; to the despite of Art, losse of precious time, and betraying of willing and industrious wits into ignorance and idlenesse."

Possibly another reason was the fear that his parishioners and others might think that he might have been better employed than inventing slide rules. Supporting this latter view is the fact that he published (1633) his "Mathematicall Recreations" under the pseudonym of Henry Van Etten. In this volume occurs the world-famous arithmetical trick, "Think on a number, double it, &c." It is highly probable that he invented it.

I see no reason for doubting Oughtred's word that he used sliding scales in 1618. The date of Wingate's reputed[2] discovery was thus anticipated by six years. A perusal of Partridge's book published in 1671 shows that the method of using compasses with Gunter's scales was the one that was then generally employed in London. In that year Partridge's slide rules were for sale at the shop of Walter Hayes, at the Cross-Daggers in More-Fields, next door to the Popes-Head-Tavern, London.

Personally, I consider that Seth Partridge is the real inventor of the modern 10-inch slide rule.

ALEXANDER RUSSELL.

The Tercentenary of the Telescope.

THE article on the tercentenary of the telescope, published in NATURE of December 16, 1909, is extremely welcome, not only because of its appositeness in point of date, but because Dr. Dreyer sets in true light the nature of Galileo's claims in connection with the discovery of the telescope. I do not think that it can be denied that Galileo himself makes the claim, for he puts into the title of the "Sidereus Nuncius" the words "nuper a se reperti." Nor can this be brushed aside as merely an elliptical phrase, because it is pretty clear that he left on the minds of the Doge and Senate of Venice the impression that he had invented the instrument with which he showed them the shipping. I deduce this from the decree as given in a footnote by Mr. Fahie on p. 78 of his admirable "Life of Galileo."

Galileo seems to have known nothing about "the secrets of perspective" as suggested in that decree; he describes quite clearly that he did not reason from optics, but from common sense; and his optics were, in point of fact, wrong when he asserted that one lens could not alone act telescopically. It seems clear that he knew nothing about the formation of an image by a lens. I confess that I cannot see that he is entitled in this matter to so much credit as Prof. Turner ascribes to him in a recent article in the *New Quarterly*.

In the matter of the satellites of Jupiter we tread on much more certain ground, since it is now, I believe, generally conceded that Marius, in his "Mundus Jovialis," gives us a genuine account of his own observations. The charge of plagiarism formulated by Galileo, and repeated by nearly all his biographers, is now exploded. (Mr. Fahie does not explicitly charge Marius with plagiarism, but clearly he disbelieves the general truthfulness of the "Mundus Jovialis," a position that, I feel sure, he would abandon if he read what Messrs. Oudemans and Bosscha have written.) Dr. Dreyer says that Marius found the satellites one day later than Galileo, but when the actual records are compared it becomes clear that Galileo was, on the contrary, at least two days behind Marius. From Galileo's account in his Italian MS. notes, reproduced by Prof. Favaro in his national edition, we see that it was on January 11 that he first suspected the three "stars" to be satellites. (The "Sidereus Nuncius" suggests January 10 for the first suspicions.) Thus Galileo saw them as stars on January 7, and as satellites on January 10 or 11. Now Marius saw them as stars some month or so earlier, and on January 8 he discovered their true nature. Thus it is hardly fair to compare the discovery as satellites made by Marius on January 8 with the mere detection as "stars" made by Galileo on January 7. For the fourth satellite Galileo is entitled to the priority.

I dislike as much as anyone all quarrels about priority, and only direct attention to these facts because of Galileo's hostile attitude. His genius and his intuitive perception of the ways of nature will gain for him for ever the admiration of all men, but his arrogance and jealousy in these two matters make it incumbent on us to be much more critical than in ordinary cases, and particularly so because such fair-minded biographers as Mr. Fahie speak of "his right to the first discovery" of the satellites, and everyone uses the phrase "Galilean telescope."

Cross-fertilisation of Sweet-peas.

UNDER the above heading a writer in NATURE of January 6 (p. 280) refers to "the statement that the sweet-pea is invariably self-fertilised," a statement which he thinks is "often based on an opinion of Charles Darwin's." In refutation of this opinion your correspondent describes the visits of the hive-bee and of Megachile to the flower in question. These same species were seen by Mr. Darwin to visit sweet-pea flowers ("Cross and Self-fertilisation," 1876, p. 156). He goes on to ask how it is that the varieties are not habitually mongrelised, and sums up his discussion in the following words:—"Whatever the cause may be, we may conclude that in England the varieties never or very rarely intercross. But it does not follow from this that they would not be crossed by the aid of other and larger insects in their native country, which in botanical works is said to be the south of Europe and the East Indies. Accordingly I wrote to Prof. Delpino, in Florence, and he informs me 'that it is the fixed opinion of gardeners there that the varieties do intercross, and that they cannot be preserved pure unless they are sown separately.'"

January 10. FRANCIS DARWIN.

MAY it be allowable to point out that "π," who has contributed an interesting note (NATURE, January 6, p. 280) on the "Cross-fertilisation of Sweet-peas," is not the same who (vol. lxxii., p. 631) is responsible for the "Rhymes on the Value of π"?

THE ORIGINAL "π."

A Hardy Goldfish.

CAN one of your readers please explain the following incident?

I keep some goldfish in a glass bowl. On December 31 last one of them was seen lying motionless upon its side on the surface of the water. After about an hour, as it was thought to be dead, it was removed to a shelf, remaining there for three hours. My sister then picked it up to throw it away, but was surprised to find it opening its mouth and breathing. She placed it in fresh water, when at first it lay on its side, occasionally moving its head and fins. The water presently appeared to be slightly tinged with the golden colour of the fish, which suddenly turned over on to its back, the ventral surface being upwards, and remained thus for some time. On being transferred to another vessel, the fish, assuming the normal position, swam about leisurely for a little while, and gradually recovered its usual energy, being now equal to any of its old companions.

Was this a case of paralysis, cramp, or other temporary ailment, and what enabled the fish to remain so long alive out of its natural element? G. C. CONSTABLE.

50 Clonmel Road, South Tottenham, January 4.

[2] "Le Calcul Simplifié." By M. d'Ocagne. (1905.)

RECENT WORK IN THE TELEGRAPHIC TRANSMISSION OF PICTURES.

COMMERCIAL photo-telegraphy may be said to have started in November, 1907, when Prof. Arthur Korn installed three of his selenium instruments at the offices of the *Lokal Anzeiger,* in Berlin, *L'Illustration,* in Paris, and the *Daily Mirror,* in London; towards the end of 1908 a further selenium apparatus was installed at Manchester. These early machines depend on the sensitiveness to light of one modification of the element selenium—selenium of the slate-grey form distributed over two platinum coils wound one between the other over a flat rectangular plate of steatite, being termed a selenium cell. Current was passed from a battery through the cell, on which was cast illumination from a Nernst lamp, the rays of which had first to pass through a revolving transparent photographic film, so that the intensity varied each instant according to the density of the photograph. A second cell was illuminated simultaneously by suitable means, the two being connected up on opposite sides of a Wheatstone bridge, so that the current sent to the receiving machine varied as the difference of the reciprocals of the resistance of the two cells. By combining suitable cells the inertia was largely overcome, and a photographic portrait could be transmitted in twelve minutes. The current at the receiving station passed into a string galvanometer, and laterally displaced a small shutter attached to the "strings," this movement cutting off more or less of the light projected from a second Nernst lamp on to a sensitive photographic film revolving synchronously with the transmitting cylinder, and one-quarter its size.

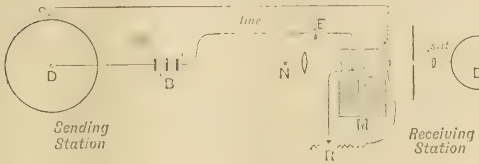

FIG. 1.

The disadvantage of this system is that the current transmitted is so small that when there is much leakage on the line it is difficult to get sufficient movement in the shutter of the galvanometer to give a useable result. The maximum current obtainable at the receiving station is about one milliampere. Prof. Korn's telautograph, which he completed in 1908, was therefore a great advance, as, the resistance of the line and the galvanometer being R and r respectively, the current C is proportional to $E/R+r$; hence by increasing the electromotive force, more current—up to 20 milliampères—can be obtained, and the induction effects from neighbouring lines are very much less pronounced.

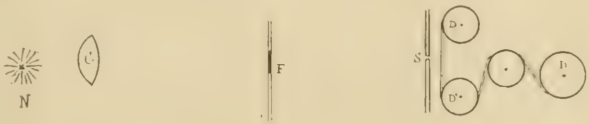

FIG. 2.

The principle of the telautograph of Prof. Korn is seen in diagram form in Fig. 1. Here D is a cylindrical drum about 10 cm. diameter and 12·5 cm. in length, which is revolved at the rate of 30 r.p.m. by a high-speed motor suitably geared down; S is a steel stylus which is mechanically moved laterally at the rate of about 1 cm. in 40 seconds, and thus S traces a spiral path over the drum D. To D is attached a piece of copper foil, on which has been drawn a sketch or copy of a photograph in some insulating ink; more recently a single line half-tone reproduction of a photograph in fish-glue on metal foil has been transmitted with considerable success. B is a battery of thirty to sixty volts, and the telephone line is represented by dotted lines. A condenser is usually shunted across SD to prevent sparking, about one microfarad being necessary. At the receiving station we have a drum D, of ebonite, on which is wrapped a piece of sensitive photographic film or paper, this revolving in a light-tight box, and also moving laterally in corresponding manner to the transmitter. In the front of the box is a lens and small diaphragm, concentrating as a small spot on the film whatever light passes through a fine slit; this slit lies on the optic axis of a condensing lens fixed in front of the Nernst lamp N, the rays of which pass through a hole bored in the pole pieces of a strong electromagnet M, absorbing about 100 watts. A fine flat silver wire is stretched across the magnetic field, as shown in the figure, through which the current received passes; the shadow of this wire, when *no current passes, i.e.* when the stylus S is separated from the metal on D by an insulating line of the picture, just covers the slit, but when the stylus is in contact with the metal, and current flows through the circuit, the wire is displaced, and light therefore falls upon the sensitive film.

If the period of swing of the galvanometer wire nearly coincides with the period n/t of the currents sent from the transmitter—n being the number of lines per centimetre and t the time taken for a point on the circumference of the cylinder to travel 1 centimetre—there is a great tendency for the wire to vibrate intensely and so not respond exactly to the widths of the lines, which widths constitute in effect the tones in the photograph. Also in transmitting a half-tone photograph with n lines per centimetre, there is always a tendency for the wire to swing with a frequency n/t. A very dead-beat effect is, however, obtained by inserting a cell in the line circuit, and shunting a regulating resistance on the galvanometer, as indicated in Fig. 1, and by keeping the moment of inertia of the string to a minimum value.

I have obtained useful photographic records of the movements of a string galvanometer of very small inertia, in the manner shown in Fig. 2. Here the light from a Nernst lamp N is projected through the hole in a string galvanometer, where it is intercepted by the magnesium shutter F attached to the strings; the shadow of the foil covers a slit S (perpendicular to the surface of the paper), and as F moves aside (when current passes through the wires), the effective width of the slit is increased; a revolving sensitive film is actuated by the drums DD, worked by clockwork. The result of transmitting a half-tone photograph, and receiving the same by optical photographic means, is seen in Figs. 3 and 4; an artificial line was used. By means of this apparatus much valuable information has been obtained relative to the effects of capacity and inductance in long cables, some particulars of which I hope to publish shortly; the effect of capacity is to widen the "teeth" and make one run into the next.

FIG. 3. A graduating tint in a half-tone photograph represented as a series of waves of diminishing intensity.

FIG. 4.—Dots of varying size in face of a portrait represented as waves with different maximum ordinates.

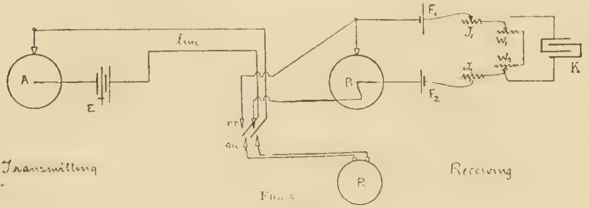

FIG. 5

The telectrograph, which is at present being extensively used for transmitting news photographs from Manchester and Paris to London, is a modification of the Bakewell apparatus, and its essential feature is the balancer or compensator for overcoming the capacity and inductance effects of the line—distortion and "leads" of waves. The apparatus is seen in Fig. 5. Here A is a brass drum to which is attached the half-tone photograph—printed upon lead sheet, and pressed therein so that an even surface is offered to the stylus, which is provided with an iridium point E is the sending battery. The current received flows into two tongues, which are ordinarily in contact with the platinum pins PP, which lead the current to the drum and stylus of the receiver, on the former of which is placed moist absorbent paper containing the necessary chemical matter to give, by electrolysis, a coloured mark when current passes through it. At the end of the revolution, which is finished *before* that of the transmitting cylinder, a metal check arrests further movement, and the motor merely revolves a friction clutch. When the transmitting cylinder has now completed *its* revolution, the tongues being now in contact with the pins QQ, a contrary current is transmitted by means of a reverser, and this passes into the polarised relay R. The relay actuates, through a local battery, a magnetic release which draws away the check, so that the receiving drum starts off again. This means of synchronising is one in frequent commercial use, and was employed by Prof. Korn in his telautograph, and (with slight modification) in his selenium machines.

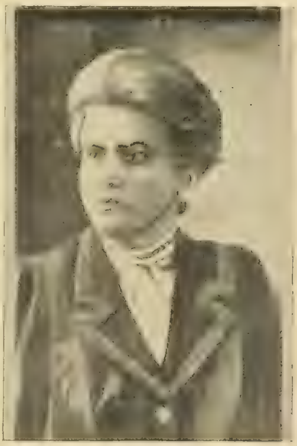

FIG. 6.—Telectrographed from Manchester to London.

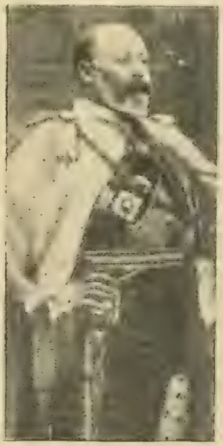

FIG. 7. Telegraphed over artificial line of 2000 Ω by Thorne-Baker telectrograph.

Now if a photograph transmitted as above be received direct on the chemically prepared paper, it would be blurred beyond recognition, owing to the distortion and the secondary discharges due to the line, A small dot would appear elongated as follows:—Where a succession of dots should be received, each one would run into the next, and if at a certain moment the action, after such a series of dots, should cease abruptly—corresponding to a "white" or "high-light" in the photograph—it would, on the contrary, not cease for perhaps a quarter of a second, a tapering chemical line trailing after the last correct mark. The balance as shown in Fig. 5 effectually stops this; two secondary cells, F_1 and F_2, are shunted on to the line through variable inductances, J_1 and J_2, and send a reverse current into the line and variable resistances, W_1 and W_2, while from the sliding contacts of the latter a variable capacity K is fitted. By carefully observing the character of the image on B during the first two or three revolutions, one can at once counteract the line effects by regulation. In the Thorne-Baker telectrograph there are seventy-five turns of the cylinder per inch travel of the stylus, and the cylinder revolves once in two seconds. A result obtained with it over an artificial line (resistance of 2000 Ω) is shown alongside one transmitted from Manchester to London (Figs. 6 and 7). Fig. 8 shows a photograph transmitted by Korn's telautograph from Berlin to Paris, and Fig. 9 a line drawing transmitted by that system over an artificial line of resistance 1000 Ω.

Experiments are at present being made to transmit pictures and photographs by wireless telegraphy, but considerable modification of the ordinary arrangements is necessary, as the number of signals to be sent per second is very much greater than in the case of word telegraphy. The problem is, in fact, comparable with that of wireless telephony, whilst synchronisation has also to be arranged. The later results I have obtained with purely experimental apparatus are sufficiently good technically to show that the problem is one within the limits of commercial practicability.

T. THORNE-BAKER.

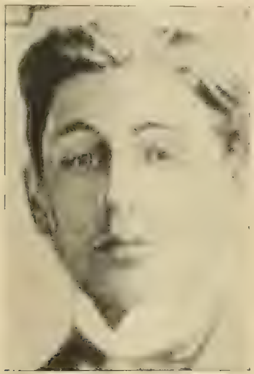

FIG. 8.—Telegraphed from Berlin to Paris by Korn telautograph.

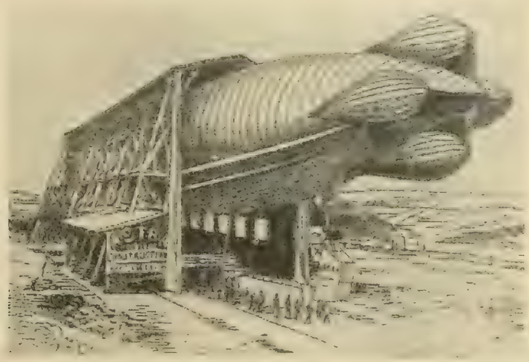

FIG. 9.—Telegraphed over an artificial line of 1000 Ω by Korn telautograph.

SIR CHARLES WILSON.[1]

THE life of Sir Charles Wilson, by his friend Colonel Sir Charles Watson, belongs emphatically to that class of biography which, as Carlyle held, ought to be written. Whether it is destined to be read by any large circle is another question. We might occupy much space in a discussion as to the exact degree of distinction in the subject that justifies a published biography were it not a question that settles itself automatically. We may, at any rate, congratulate the future historians of the Victorian and post-Victorian epochs in that they will have to look for their raw material, not among dusty and almost illegible manuscripts, but plainly set out in fair print and duly classified and catalogued by the librarians. Of such materials as this "Life" will future history be made.

Wilson's career was one of those which are still common in this country, but tend to get rarer and rarer with the advance of democratic ideals, a career devoted to the public service, and of the highest usefulness, unrecognised by, and almost unknown to, the ordinary world of newspaper readers. We might, if inclined to a satirical vein, say that its very obscurity is the best evidence of the value of such a career, seeing that it is often only on some shortcoming, either actual or supposed, that the outside world becomes conscious of the existence of the man in question. Thus in Wilson's case, were it not for the accusations, long since withdrawn as totally unfounded, of a failure on his part to do all that was humanly possibly to relieve Khartum before its capture by the Mahdi, his name would possibly be little known.

Passing over the period of childhood and adolescence and his entry into the Royal Engineers, the first important post that Wilson filled was that of secretary to the British Commission for delimiting the boundary between the United States and Canada from the Lake of the Woods to the Pacific along the 49th parallel of latitude. This line was marked out by astronomical methods, a procedure now known to be liable to the defect that the observations at each station are subject to an unknown error due to the force of local attraction or the deflection of the level. At the present day such a line would be delimited by means of a triangulation. In 1858, however, survey methods had not developed enough for this to be practicable, at all events within any reasonable limit of time, and the only possible course was taken. That the line as then marked out, and as it remains to this day, was not a true parallel of latitude, but a wavy line departing from the truth to distances of some hundreds of feet on either side, was of secondary importance. The urgent point was to get some acceptable boundary laid out upon the ground, and so marked that nobody could have any doubt as to which side of the line they were on at any given moment.

With the technical work of the Commission in the field, Wilson had, however, little to do; his duties were of a more arduous character. The country traversed by the line was in parts almost unknown, and, as regards all the western section, of an extremely wild and mountainous character. The [illegible] were very severe, and the difficulties of travel formidable. In such circumstances it may well be understood that the responsibilities of Wilson's position, being then little more than a boy, entrusted with the duties of commissariat, store and transport officer, were great.

Jebel Musa.

Jebel Serbal.

The Problem of Mount Sinai. From "The Life of Major-General Sir Charles William Wilson."

Not long after the termination of this commission, he had an opportunity of taking up a work of a somewhat different character, a work which at intervals occupied his energies for a large part of his life—the survey of Palestine and the surrounding regions. It is not the place here to recapitulate, even in briefest summary, the services rendered by him and other officers in this great undertaking; those curious may consult the maps and records of the Palestine Exploration Fund, or may read the account of Wilson's share of it in the work before us.

After his return to England in 1866, and his marriage in 1867, he again went to the East to carry out a special task for the same body, the survey of the Sinaitic Peninsula, with the object of illustrating and elucidating the events of Bible history. Preeminent among the points to be investigated was that of the identification of Mount Sinai, then a disputed question, some authorities contending for a mountain called Jebel Musa, and others for Jebel Serbal. Wilson's party, including, it should be remembered, the late Prof. E. H. Palmer, afterwards murdered by Bedouins in the same country, unanimously came to the conclusion that Jebel Musa was the true Sinai of the Exodus. This view is now generally accepted, and it is this mountain which is pointed out to passengers in mail steamers proceeding southward from Suez. The late Sir Richard Burton, however, always refused to accept it, and maintained that the honour belonged to one of the minor peaks to be found along the pilgrim road from Suez to Akaba.

Wilson's share in the Nile expedition of 1884, and in the attempt to relieve Khartum and rescue Gordon, is dealt with at length. We have already alluded to the abortive attack upon him for a failure in no wise his fault, and it may be fairly conjectured that the author, himself a life-long friend of Gordon, welcomed this opportunity of putting on record his version of the history of that troubled time, especially so in view of the opinion strongly held by him that Lord Cromer, in his "Modern Egypt," was less than fair to Gordon, and gave evidence of a certain want of understanding of his character.

The other work that filled Wilson's busy life we must pass by with slight notice. In 1878 he was appointed to delimit the Turco-Servian frontier, and he afterwards served as Consul-General in Servia. He was for seven years, 1886–94, Director-General of the Ordnance Surveys, a post that he filled with efficiency, though his rule was not marked by any striking advances. From 1895 to 1898, the date of his retirement from the army, he held the office of Director of Military Education. After his retirement he twice again visited Palestine, and in 1901 was elected to the chairmanship of the executive committee of the Palestine Exploration Fund, a position which he held until his death in 1905. He was the recipient of numerous honours, being elected a Fellow of the Royal Society in 1874. The present biography is written in a simple and unpretentious style. It may be cordially recommended to all those to whom the history of the events of which it treats is of interest. The general reader may also find a certain attraction in this account of a man who possessed a personality of rare charm, and, without any commanding intellectual equipment, lived a life of high accomplishment.

E. H. H.

TECHNOLOGICAL SCIENCE IN GERMANY.

WHAT are the chief causes to which the remarkable industrial progress made by Germany in recent years is attributable? This is the question M. E. Leduc sets himself to answer in a paper[1] which, though written primarily for his compatriots, is also of much interest to others.

On the morrow of Jena the outlook in Prussia was sorry indeed. The country was poor, the population sparse; there were no manufactures, and not much commerce. Few roads, and those bad; an ill-equipped postal service; little money, and the kingdom ringed around with tax-offices: such is the picture drawn of the land which lay there bleeding after Napoleon's victory in 1806. Yet now, little more than a century after, the vanquished of Jena have not only ousted their conquerors from the position of military predominance, but are steadily forcing them, and others, from their coigns of vantage on the fields of industry and commerce.

M. Leduc first outlines the earlier steps which led to this industrial advance—the revival of national sentiment, the removal of class barriers and other mediæval restrictions upon freedom—and then deals at length with the two causes which he holds to be the principal factors in the great modern expansion of German commerce, namely, education and cooperation.

By "education" here is meant education in applied science. First, as regards the teacher; the ideal is a man possessing a thorough knowledge of his subject, a teaching aptitude, and a certain quality of industrial practicality. This last is the touchstone. In technological training the aim should be to impart the scientific spirit rather than to let the student lose himself in "pure" science. Otherwise his intellect is apt to become somewhat mummified; and so far as industrial fertility is concerned he presently, college days being over, comes to resemble the fig-tree of scripture, which bore nothing but leaves.

This leaven of practicality is traceable in all the German technical science training. The professors at Charlottenburg are not merely college dons; some, for example, are chiefs of factories, others are the proprietors of commercial laboratories. The students in the technical institutes brew beer, distil spirits, and bake bread, all on a manufacturing scale, and all for sale in the ordinary way of trade.

From the description given it appears that the German instruction in technological science may be broadly classified into four divisions. First, there is the comprehensive training which is to turn out the future captains and leaders of industry. Next, provision is made for putting trustworthy information on technological matters at the disposal of the trading community. Thirdly, central institutions are established where certain industries—*e.g.* brewing, sugar-production—are studied scientifically and practically. Fourthly, there are local technical schools adapted to the special needs of particular localities.

Under the first category comes the famous High School of Technology at Charlottenburg. Here a complete course of instruction in any of the leading branches of technology is obtainable. The scale upon which the institution is equipped may be best shown, perhaps, by the following summary of the professorial staff:—

Section	Professors	Privats-docent
Architecture	21	12
Civil Engineering	13	8
Mechanical Engineering	20	14
Maritime Engineering and Naval Construction	6	1
Chemistry and Metallurgy	15	20
Mathematics and Natural Science	18	15
Foreign Languages	4	—
	97	70

In M. Leduc's opinion, specialisation and the more definitely practical character of the instruction are the points on which the German system shows itself superior to the French. It was all very well a century ago to say "Technical science is one subject; every manufacturer must know it in all its branches or be dubbed incompetent"; but this, like other formulas, has become antiquated, and the world has outgrown it.

Supplementing the tuition in technological science indicated above comes the work of the laboratory at Gross-Lichterfeld. This is a large establishment, covering an area of 10,360 square metres. Its duties are (*a*) to carry out researches, and to make examinations and analyses of materials both for public departments and for the trading community, issuing certificates and valuations based upon the results obtained; and (*b*) to arbitrate, on request of both parties, in matters of litigation concerning the composition and properties of commercial products. In addition, practical instruction in the testing of materials is given to certain students from Charlottenburg; and, as far as circumstances permit, assistance is rendered to persons pursuing special researches. Fixed fees are payable for the services of the laboratory; and the certificates issued are commonly used in commercial transactions as proof of the composition and properties of the articles described upon them. There are six sections, dealing respectively with metals, building materials, paper and textile fabrics, oils, general analytical chemistry, and metallography.

In the third class come the special institutes devoted to various agricultural industries; for example, sugar production, brewing, distilling, milling, and baking. Each of these has its institute, splendidly—nay, lavishly—equipped, not only for the training of students, but for research into any special problem of the industry. One feels, says M. Leduc, speaking of the sugar institute, that money without stint has been given to assemble here everything required for the study of beet-sugar production, and everything is the most perfect of its kind.

Now, in its origin and development this industry is notably a French one, yet Germany has outstripped France in its exploitation, and produces nearly three times as much sugar. Why? Because in Germany the production is organised and unified. "Germany is the land of cartels; jealousy of one's neighbour is unknown. The sugar factories all accept one and the same guidance, namely, that given them by the Institute at Berlin, which is richly endowed by the manufacturers. Prof. Herzfeld, to whom neither money nor help is begrudged, studies for all, and everybody profits thereby."

Similarly in the milling and baking industry, important problems have arisen which could not be authoritatively solved by practical experience only. It was recognised that, as in other industries, the one condition of progress was the founding of an institution devoted solely to the study of cereals, and in which every detail of the questions at issue could be submitted to rigid experimental investigation. Accordingly the required institute was established. It was erected at the expense of the State, but receives subventions from the Chamber of Agriculture, the Society of Millers, and others.

---

[1] "L'Organisation syndicale et technique en Allemagne." By M. E. Leduc. (Bulletin de la Société d'Encouragement pour l'Industrie nationale, Octobre, 1909.)

Finally, for the specific assistance of certain local industries, technical schools exist, the particular instances quoted being the professional college of ceramics at Buntzlau and a similar but more restricted institution at Lauban. The instruction here is less generalised than at Charlottenburg, the aim being to impart an artistic and technical education suited to the special requirements of the locality.

As regards cooperation, a good deal is said, but we are only concerned here with its bearing upon technological progress, not with its purely trade aspects. Associations of manufacturers are formed, and if, for example, it is required to carry out some special research, they may give subventions for the purpose to technical colleges or to individual experts; or a commission may be nominated to make experiments; or chemists and engineers may be dispatched abroad to study new processes and new apparatus. Thus even a small manufacturer can keep himself abreast of progress in his department, and researches altogether too costly for single firms can be carried out by spreading the cost over the whole association. As concrete examples may be mentioned (1) the makers of explosives, who maintain an experimental laboratory with firing ground and testing station at an annual cost of 200,000 marks; and (2) the association of Portland cement manufacturers, who, for the reputation of German cement, make stipulations as to quality, and support a laboratory where each member's product is examined to ensure that it conforms to the requirements.

Lack of space forbids us to follow M. Leduc further in his study of this most interesting question, but the keynote of the whole matter is organisation. There is first an intelligent appreciation of the benefits which science can render to industry; next a liberal but carefully-bestowed provision for instruction of her sons in the applications of science; and then, by her organised system of trade syndicates, Germany pushes home the advantage gained through her equally well-organised system of technological education.

C. SIMMONDS.

PLAGUES OF LOCUSTS IN SOUTH AFRICA.

FOR the past three years an organised effort has been made by the Governments of the South African colonies to destroy the swarms of locusts that from time to time invade the cultivated districts and ravage the crops. The third annual report of the Central Locust Bureau has lately been issued under the editorship of Mr. C. P. Lounsbury, the entomologist for the Cape.[1] Together with the two previous reports it furnishes a very instructive demonstration of what can be done by enlightened executives working harmoniously on scientific principles. The Central Bureau comprises representatives of the Cape, Natal, Transvaal, Orange River Colony, Southern Rhodesia, Bechuanaland, Basutoland, Swaziland, Mozambique, and German South-west Africa, its influence thus overstepping political boundaries. It acts by collecting and spreading information about locusts and their migrations throughout the district of its operations, the actual work of repression or extermination being undertaken by the local governments separately.

Two species of locust periodically become serious plagues in South Africa. The red-winged locust (*Cyrtocanthacris septemfasciata*) infests, in various seasons, the east coast districts, migrating in spring and summer, and retiring to the forests in winter. The young locusts are active and most destructive during January and February. No serious invasion of this species was observed in Natal and the neighbouring districts between 1846 and 1893. Whence the migrating swarms come has not been certainly determined, but the Zambezi region is regarded as their probable home. Since 1893 there have been several plagues of this locust in the British colonies, notably in 1907–8, when more than 33,000 swarms were destroyed in Natal. During 1908–9 the insects were by far less numerous; nevertheless, it is computed that a loss of 250,000*l.* from damage to crops was prevented by the exertions of the locust officers.

The brown locust (*Pachytylus sulcicollis*) has its headquarters in the Kalahari Desert, whence swarms migrate into the settled central regions of the South African colonies. The eggs of this species are laid in winter, and are incited to hatch by the influence of the summer rains. Dry conditions lead to postponement of hatching, possibly for a term of more than three years, and such "suspension of animation" is obviously of advantage to a desert-haunting species. Like the red-winged, the brown locust was less numerous and destructive in 1908–9 than in 1907–8, which seems to have been a year of exceptionally severe attack. In March of last year, however, enormous swarms of this species invaded Cape Colony from the north, overspreading an area of 125,000 square miles, so that during the summer of 1909–10 great care and energy will be needed to keep the pests in check.

According to Mr. Lounsbury, no preventive measures can be taken in the "uninhabited and practically waterless wastes" whence the great swarms migrate into the colonies. Attention must be directed to the destruction of the young locusts hatched from the eggs laid by these winged swarms. The young insects during their preparatory stages, while the wings are still undeveloped, are known as "hoppers" or "voetgangers" by the English or Dutch farmers. It is these young locusts that ravage the crops to so terrible an extent, and if the insects be left alone, successive generations may follow each other in the settled districts that are invaded. The farmers, therefore, assisted by the Government, are urged to make war on the "hoppers." Burning grass lands, and poisoning with a sweetened solution of soda arsenite, are the means of combat now in general use. During the locust-campaign of 1907–8, forty-three tons of soda arsenite, ninety-eight tons of sugar, forty tons of treacle, 150 water-tanks, and 5000 pumps were provided, and nearly 12,000*l.* was expended.

In his warfare against the locusts, man finds valuable allies in several species of birds, which pursue the locust swarms, and sometimes well-nigh exterminate them. Kestrels, the "locust bird" (*Glareola melanoptera*), and the white stork are especially active as locust-eaters. It is of great interest to find that two white storks observed devouring locusts in Basutoland in January, 1909, bore leg-rings with inscriptions showing that the birds had migrated from northern Germany in the preceding autumn.

G. H. C.

---

[1] Third Annual Report of the Committee of Control of the South African Central Locust Bureau. Edited by Charles P. Lounsbury, Government Entomologist, Cape of Good Hope. (Cape Town, 1909.)

NOTES.

Three British expeditions are likely to be engaged in the exploration of the Antarctic before long. In April last Dr. W. S. Bruce described his plans for a Scottish Antarctic expedition; in September Captain R. F. Scott appealed for support for an expedition which will leave London in July next; and Sir Ernest Shackleton, who has been presented with the Nachtigall gold medal of the Berlin Geographical Society, announced in a speech at Berlin on January 9 that he proposes to begin the preparations for a new expedition when he has completed his work and lectures relating to the achievements of the last expedition. Captain Scott has just received a letter from the Treasury informing him that Parliament will be asked next session to vote a sum of 20,000*l.* towards the cost of his expedition to the South Pole. The sum he asked for in appealing for funds was 40,000*l.*, and the total amount now subscribed and promised is 31,000*l.*, so there should be no difficulty in raising the additional 9000*l.* before the expedition starts. In all probability the amount originally asked for will be considerably exceeded. The expedition will sail in the *Terra Nova*, and the money already subscribed is sufficient to equip the vessel for her voyage. After departing from London the ship will call at Cardiff for coal, and will then proceed south *via* the Cape and Australia and New Zealand, and will leave the last-named place for Antarctic regions early in December. Though the undertaking is described by Captain Scott as "an all-British expedition," it is unfortunate that the announcement of the proposed Government grant of 20,000*l.* has been received with mixed feelings by geographers in Scotland. A circular letter which has reached us from Mr. J. G. Ferrier, secretary of the Scottish Oceanographical Laboratory, Edinburgh, deplores the fact that last November Dr. Bruce was refused a Government grant toward the equipment of an Antarctic expedition then being organised in Scotland, though in the words of Prof. James Geikie, president of the Royal Scottish Geographical Society, "no one is better fitted to carry such an enterprise to a successful conclusion, and the scientific results he has obtained have not been surpassed in interest or importance by the work of any living explorer in high latitudes." While we gladly acknowledge that Dr. Bruce has done splendid work in Antarctic regions with limited means, and regret that Government support for the proposed Scottish expedition has not been forthcoming, we think that in a matter of this kind it is undesirable to appeal to the Scottish public "to stand up for this and other Scottish rights." The claims of an expedition to support from the State for Antarctic exploration must surely be scientific and not political. Because we have confidence in Dr. Bruce's scientific ability and experience we trust that the funds will be provided for the expedition he is organising. Three British expeditions approaching the highest southern latitude from different bases would make for national credit and scientific progress.

The annual general meeting of the Iron and Steel Institute is to be held at the Institution of Civil Engineers, London, on May 4 and 5, and the autumn meeting at Buxton on September 27–29 next. The council of the institute will proceed shortly to award Carnegie research scholarships, and application must be made before February 28. The awards will be announced at the autumn meeting.

A company is being formed in America by Dr. Aaron Aaronsohn, a Turkish agronomist, to investigate the agriculture of Palestine with the view of finding plants that will resist drought in the United States. The inquiries will be carried on through an experiment station at Haifa, which will exchange information with the Department of Agriculture at Washington.

The death is announced at Bayonne, New Jersey, of Mr. William Abner Eddy, in his sixtieth year. In 1890, while engaged as an accountant, he began the aërial experiments which made his name widely known. These included some of the earliest attempts at photography from kites and at measuring by the same means the temperature at various heights. In 1903 he experimented with model aëroplanes dismissed from the lines of kites in mid-air. Mr. Eddy also invented various devices for measuring the tremors of the earth.

The Civil Service Commissioners announce that an open competitive examination for not fewer than three situations as cartographer in the Hydrographic Department of the Admiralty will be held in July next, and that copies of the regulations and syllabus may be obtained at once from the secretary, Civil Service Commission, Burlington Gardens, London, W. Forms of application for admission to the examination will be ready for issue towards the end of January, and will then be obtainable on request, by letter, addressed to the Secretary of the Civil Service Commission.

The opening lecture on January 6 of a course on parasitology, which Prof. R. Blanchard is delivering at the Paris Medical School, was made, the Paris correspondent of the *Times* reports, the occasion of a demonstration of the cordial relations existing between French and British men of science. Prof. Blanchard devoted the lecture to an account of the progress made by British men of science, and especially by the Liverpool School of Medicine, in parasitology and in the treatment of tropical diseases. Since the foundation of the Paris Institute of Colonial Medicine in 1902 through the initiative of Prof. Blanchard, friendly relations have been maintained between it and similar institutions in England and in Brussels, Hamburg, Lisbon, Naples, and Philadelphia. In 1903 pupils of the Paris institute visited the London school under the guidance of Prof. Blanchard, who has been to London and Liverpool several times. Sir Rubert Boyce, professor of pathology in the University of Liverpool, was present, and met with a flattering reception. In expressing his thanks, he dwelt on the importance of the work of Prof. Blanchard and his pupils in furthering the advance of parasitology.

By the death of Colonel George Earl Church, on January 4, science has lost one of the most striking representatives of geographical studies in this country. He was born in Massachusetts, U.S.A., in 1835, and was educated as a civil engineer. In his twenty-third year he took part in a scientific expedition to South America, and was in later life closely associated with that continent. After distinguished service in the American Civil War and the Mexican campaign of 1866–7, he devoted himself to the problem of opening up communication between Bolivia and the Atlantic, and reached the Bolivian plateau by way of the Madeira and Mamore. Having satisfied himself that by the construction of a short line of railway round the cataracts of the Madeira a large area of Brazil and Bolivia would be opened to commerce, he obtained a concession, funds were raised, and work commenced. Unfortunately, as a result of malaria, financial and political intrigues and litigation, it was found impossible to carry out the undertaking, and the ruins of the abandoned railway remained an object of melancholy interest to travellers until in recent years the construction of the line was once more put in hand. After a successful career, during which he was engaged in advising on or carrying into execution important operations in different parts of the world, he took up his residence in this country. He contributed some suggestive papers to the *Geographical Journal*, including one on the physical geography of South America, and as president of the Geographical Section of the British Association delivered an address on the ancient Pampean Sea of the Argentine. He will best be remembered for his contributions to the discussions of the Royal Geographical Society, in which he entertained his audience from his inexhaustible stores of personal reminiscences and historical reading. He served on the council of the society, and held at one time the position of vice-president.

THE first part of the fortieth volume of Gegenbaur's *Morphologisches Jahrbuch* contains an exhaustive treatise, by G. P. Frets, on the lumbo-sacral plexus of monotremes, which will be indispensable to all future students of this extremely variable part of the nervous system. By way of comparison, the author also deals with certain other forms, notably Sphenodon, giving a detailed account of the myology of the hinder extremity in this important type.

THE sixth part of the *Sammlung anatomischer und physiologischer Vorträge und Aufsätze*, edited by Profs. Gaupp and Nagel, consists of an interesting memoir, by Dr. H. Schridde, on "Die ortsfremden Epithelgewebe des Menschen." The author deals with epithelial abnormalities of various kinds, and endeavours to interpret them in a philosophical spirit from the points of view of phylogeny and ontogeny. His observations have thus more than a merely medical interest, although no doubt they will be appreciated mainly by the student of cellular pathology.

THE *Quarterly Journal of Microscopical Science* for December, 1909 (vol. liv., part iii.), contains the third part of Dr. Gordon Hewitt's important memoir on the structure, development, and bionomics of the house-fly. A short account is given of the part played by flies in the dissemination of disease, which we could wish to see republished in a popular form and distributed broadcast. It is difficult to exaggerate the danger to which human beings expose themselves by uncleanly habits in relation to filth, food, and flies, and it is equally difficult to comprehend the indifference which even "educated" people show on this subject—except as the result of gross ignorance and want of observation. The information which Dr. Hewitt has collected with regard to the mutual relations of flies and soldiers in camp, and flies and typhoid patients in hospitals, ought to be sufficient to convince anybody who does not at once set it aside as too nasty for consideration. Unfortunately, the study of nastiness is a necessary preliminary to its removal.

IN view of the renewed interest which has lately been manifested in the difficult problem of the origin of vertebrates, zoologists will welcome Prof. MacBride's contribution to the subject in the *Quarterly Journal of Microscopical Science* (vol. liv., part iii.). Though dealing primarily with the formation of the layers in Amphioxus, this paper includes a discussion of the corresponding processes in the higher vertebrates, with special reference to the views recently expressed by Prof. Hubrecht, with which Dr. MacBride by no means agrees. We must note the addition of two new inmates to the zoological Noah's Ark of imaginary animals, viz. the "Pleuronectid" ancestor of Amphioxus, which, with a number of enormous round holes on its flattened back to represent gill-slits, appears none too well adapted to its environment, and "the common ancestor of Vertebrata, Enteropneusta and Echinodermata," which looks like a mixture between several well-known larval forms. Whatever reception they may accord to these imaginary ancestors, however, most zoologists will probably be grateful to Dr. MacBride for his expressed opinion that, "in starting with Mammalia, and reading their complicated processes into the development of lower Vertebrata, Prof. Hubrecht has read the book of vertebrate development upside down."

A COPY of the Johns Hopkins University Circular, Medical Department, has been sent to us. It corresponds to our calendars or prospectuses, and contains full details of the courses of instruction given, with fees and time-table, and a list of graduates, endowments, publications by graduates, &c. It is published by the University, and can be obtained on application to the registrar.

BULLETINS Nos. 11 and 12 of the Sleeping Sickness Bureau have been issued, and contain full and useful summaries of various papers on trypanosomes and trypanosome diseases, and their agents of transmission. We would suggest that it would be a convenience to readers if the bulletins were issued with cut edges. The director will be glad to receive early copies of authors' papers for notice and for the library of the bureau.

WE have received a reprint of an article by Arthur Macdonald from the *Journal of Inebriety*, Boston, 1909, on the statistics of alcoholism and inebriety, which gives a useful summary for various countries. We are surprised to see it stated that drunkenness in London has risen from 537 to 566 in 1890–5 to 898 in 1904 and 859 in 1905 per 100,000 of population. Certainly the police-court records show the reverse, viz. a decline in drunkenness.

THE Johns Hopkins Hospital Bulletin for December, 1909 (xx., No. 225), contains another contribution on the subject of the ancient medical writers, essays on which have appeared in that journal from time to time. Prof. Eugene Cordell writes on Aretæus, the Cappadocian who lived probably in the second century of the Christian era, about the time of Galen. Many of his works are now lost, but such as remain portray very exactly the symptoms of disease, *e.g.* tetanus, epilepsy, and hysteria. He recognised the "murmur" of heart disease, and treated phthisis by life at sea.

IN a leaflet entitled "A Plan for the Study of Man," by Mr. Arthur Macdonald (from the Proceedings of the Imperial Academy of Sciences, St. Petersburg), an apparatus for the measurement of pain is described. This "temporal algometer" consists of a brass cylinder with a steel rod running through it. The rod is supported by a spring, so that varying pressures from 0 to 4000 grams may be applied, the amount being indicated by an attached scale. The rod has a disc 15 mm. in diameter, and covered with flannel at the end. It is applied over the temporal muscle; as soon as the subject feels the pressure to be in the least disagreeable, the amount of pressure applied is read on the scale.

WE have pleasure in directing attention to the artistically designed "Nature Calendar" published by Messrs. George Philip and Son, Fleet Street, E.C., at the modest price of sixpence. Horticultural notes, observations on the movements of birds, and hints for the collection of Lepidoptera are the features of this year's issue. Special notes for the months refer to varying aspects of the weather in relation to outdoor phenomena and animate nature. The calendar is very suitable for the study and class-rooms where natural science is taught, both for the information supplied and as a suggestion for children to draw up a calendar for themselves.

OWING to the want of agreement between recent investigators of species of Isoetes, any additional information derived from the examination of different species, as the account by Miss A. G. Stokey in the *Botanical Gazette* (April, 1909), is of direct interest to botanists. The anatomy of four American species was investigated. The chief point of originality lies in the interpretation of the so-called "prismatic layers" formed centripetally by the cambium; the author dissents from the explanation, first offered by Russow, that certain of these cells are phlœm elements, but regards the whole of the prismatic layers as secondary xylem. With respect to the phylogenetic position of the genus, the author favours affinity with the Lepidodendreæ, on the ground of morphological characters.

THE identification of the lichens collected during the second Norwegian Arctic Expedition in the *Fram*, 1898 to 1902, chiefly by Mr. H. G. Simmons, was entrusted to Dr. O. V. Darbishire; the results are embodied in Report No. 21 of that expedition, together with a systematic enumeration of all the species—about 500—recorded from the Arctic regions exclusive of Alaska. The material brought on this journey from Ellesmere Land and King Oscar Land yielded more than a thousand specimens, from which 161 different species have been obtained, including the types of eight new to science. The fruticulose lichens play an important part in the vegetation; the various species of Cetraria occur in large quantities over wide areas. It is noted that no specimen of the reindeer moss was collected. The author institutes a comparison between the lichen flora of the Arctic regions, Germany, and the Tyrol to point out that nearly three-fourths of the species are found in the Tyrol and two-thirds in Germany.

THE *Kew Bulletin* (No. 9) opens with an article by Mr. W. J. Bean providing garden notes on some of the newly introduced trees and shrubs collected by Mr. E. H. Wilson in western and central China at elevations ranging from 2500 feet to 10,000 feet. A primary object of Wilson's expeditions was to introduce ornamental horticultural novelties in the shape of arborescent plants that would be hardy in the British Isles. Many of the plants raised from seed have already survived the rigours of more than one English winter. The plants selected for description are almost entirely monotypical genera. Another article by Mr. Bean refers to the Canadian wild rice, *Zizania aquatica*, recommending it for trial as an ornamental plant in ponds and backwaters. It is an annual requiring plenty of sunshine, and it is especially necessary to keep the seeds moist between collection and sowing. Dr. O. Stapf contributes an article on the perennial species, *Zizania latifolia*, which is cultivated in China for use as a vegetable, but cannot be recommended as an ornamental plant.

THE annual report from the Experiment Station, Tortola, Virgin Islands, records a year of steady progress. In the cotton industry the export of lint amounted to 52,528 lb., an increase of 2500 lb. over the preceding year. A lime industry on similar lines to the cotton industry has also been successfully started, the fruit being purchased from peasants at the experimental station. The Agricultural Department not only gives advice and assistance, but forms a direct market for much of the produce raised in the islands.

LUCERNE-GROWING in South Africa has, according to the *Agricultural Journal of the Cape of Good Hope*, recently suffered from a stem-infesting nematode, viz. *Tylenchus dipsaci (devestatrix)*, which has hitherto not appeared in South Africa, although well known in Europe. The adult worm is a fifteenth of an inch long, and produces characteristic distortions and discolorations in the plant. Infested shoots only grow out a few inches; the whole plant languishes and dies in the course of about a year. The infection spreads in a variety of ways, and in time the entire crop is so badly attacked as to be not worth cutting or feeding off. Up to the present no successful means of combating the pest is known.

THE *Agricultural Journal of India*, issued from the Research Institute, Pusa, differs from most of its kind in that it is intended for the intelligent non-technical reader and therefore appeals to a wider class than the more technical memoirs issued from the same institute. One of its most interesting features is the description of native methods of cultivation, management of crops and of stock. In the current issue the Kachin cultivation of tea is dealt with. In other articles an extension of the area under fibre plants is urged, and methods of growing lucerne are described. Mr. Maxwell-Lefroy has a suggestive paper on the cultivation of shellac. The scale-insects of the genus Tachardia, which form shellac as a resinous covering, live on a variety of trees and suck out the sap; they occur to a very great extent in Indian forests, and are, indeed, already cultivated to some extent.

THE reports on the Botanic Station Experiment Plots and Agricultural Education, Antigua, are to hand. There has been a shrinkage in the number of acres planted in cotton in the island to one-third what it was last year, chiefly because of bad seasons and insect pests. Details are given of experiments with sweet potatoes, yams, and other crops. The sugar-cane experiments are carried out on an extensive scale, there being more than 1100 plots of varieties of canes and 256 plots of manurial experiments. Some interesting results are expected from the work on limes and broom-cotton. A new industry, the production of cocoa-nuts, has been started and promises success in certain districts where the conditions are favourable. The report from St. Kitts-Nevis also shows a great amount of activity; the principal industry being sugar production, much attention is given to experiments with the sugar-cane. A good deal of work is being done in cotton, now an established industry in the presidency, and likely to be of considerable economic importance. The report from Grenada deals with cacao, rubber, Sea Island cotton, and other crops. Some interesting experiments are recorded on mulching cacao, but the problem is not yet solved, because of the difficulty of getting plants to grow in the shade of a cacao plantation.

ATTENTION is directed in a recent number of the *Agricultural News* to the fact that about 20 per cent. of the bananas grown in banana-producing countries are unfit for export, and are often completely wasted. Attempts to make a saleable product by drying the fruit and producing banana flour have been only partially successful. Experiments made at the Central Laboratory, Guatemala, described at length in the *Journal d'Agriculture Tropicale*, have shown how to obtain from this waste material a spirit resembling whisky in flavour. The yield of spirit from each bunch of bananas is estimated at 4½ litres, and the cost of manufacture is said to be much less than that of whisky. Over a period of two years the process has proved to be a commercial success. A very similar problem is discussed in the *Journal of Agriculture of South Australia.* The production of raisins has exceeded the local consumption, and as there is no prospect of a successful export trade, some new outlet has to be found. Experiments have therefore been made to ascertain whether raisins could be utilised in satisfying the local demand for strong spirit. Prof. Perkins's results led him to conclude that 150 to 154 gallons of proof spirit might be obtained from a ton of first-grade raisins, and 130 to 134 gallons from a ton of second-grade raisins, and he adds that on this basis raisins should be worth to the grower not much less than 20*l.* a ton.

Bulletin No. 399 issued by the United States Geological Survey contains results of spirit-levelling carried out by the Survey in western Virginia during the years 1896 to 1908, with the cooperation of the West Virginia Geological Survey after 1901. The results have been compiled by Messrs, S. S. Gannett and D. H. Baldwin, and include all previously published data along with the newer observations, re-adjusted and re-arranged by quadrangles. Descriptions and elevations of bench-marks are given for forty-eight counties, furnishing vertical control for nearly half the State.

In a paper published by the Department of Agriculture and Technical Instruction for Ireland (Fisheries, No. 7) Mr. C. M. Cunningham discusses the results of investigations on the drift of the Irish Sea made with floats of various kinds. The floats were distributed by making use of the many steamship lines radiating from Belfast and crossing different parts of the area under examination, and the experiments extend from June, 1903, to May, 1906; the total number of floats distributed was about 1200, and almost exactly half these have been found and the cards returned. The general result suggested is that there is a northward drift throughout the year, modified by a southward tendency during certain states of the weather, especially during the months of March, April, May, and June, when northerly winds are most apt to assert themselves. No instrument distributed north of a line joining Cork Harbour and the Land's End has been found to the south of it.

Mr. D. W. Johnson contributes an interesting study of hanging valleys to the Bulletin of the American Geographical Society. Excluding the types of hanging valleys which are not definitely related to a main stream and its tributaries, as, for example, the valleys left hanging by the encroachment of the sea on south-east England and north-western France, and valleys raised above the level of adjacent plains by up-faulting, the author discusses the questions:—(1) are hanging valleys a trustworthy indication of glacial erosion of the main valley? and (2) may not hanging tributary valleys result from glacial widening of the main valley, instead of from glacial deepening? The investigation goes to show that hanging tributary valleys may be produced independently of glacial erosion, but valleys of this type are of rare occurrence, and that wherever the mouth of a hanging valley has been materially altered to the typical glacial trough form we must infer a greater or less amount of glacial deepening.

From the Survey Department of Egypt we have received a copy of "An Almanac for 1910," compiled at the Offices of that department, and published by the National Printing Department, Cairo, at the price of 25 millièmes (6*d.*). For anyone at all interested in Egyptian affairs this almanac is full of interesting information concerning the various Government departments and services, the railways, telegraphs and population, the meteorological elements and the rise of the Nile at various places, the geographical coordinates of the principal towns, &c. General and scientific matters are also well represented by conversion tables, ephemerides, &c. The ephemeris for Halley's comet is accompanied by figures showing its brightness on different dates and its times of rising and setting. A comprehensive index concludes this cheap and useful work.

An interesting article, by Mr. R. H. Curtis, on the development and standardisation of sunshine recorders appears in *Symons's Meteorological Magazine* for November and December, 1909. The instrument first in use consisted of a hemispherical wooden bowl with hollow glass ball filled with water, invented by Mr. J. F. Campbell about fifty-six years ago, in which the charred wood gave a six-months' record, from solstice to solstice. A regular daily record was first obtained at Greenwich Observatory in 1876 by using a metal bowl, presented by Sir W. Armstrong, and a narrow strip of blackened card. So far as ordinary observers were concerned, there was some difficulty in the adjustment of the card, but this was overcome by Sir G. G. Stokes in 1879, who developed the Campbell-Stokes recorder and cards now in general use; only some trivial additions for adjustment have been made since, one of which is due to Mr. Curtis. Owing to the cost of this instrument, Mr. J. B. Jordan introduced a very ingenious photographic recorder in 1885, but the two forms of instrument do not register precisely the same thing, and after careful comparisons had been made of the results, the Meteorological Office decided to publish only the records of the burning instrument. A report upon the instruments is contained in the Quarterly Journal of the Royal Meteorological Society (vol. xxiv., p. 1), and the specification for the standard instrument has, with slight variation, been printed in the "Observer's Handbook," published by the Meteorological Committee. For obtaining uniformity of results, Mr. Curtis lays great stress upon the necessity of using cards of colour and texture similar to patterns preserved in the Meteorological Office. Other recorders, not in such general use, are not referred to in this article.

Bulletin No. 395 of the U.S. Geological Survey contains an elaborate investigation, by Profs. Schlundt and Moore, of the radio-activity of the thermal waters of Yellowstone National Park. One of the most interesting points brought out is that the travertine of the old terraces contains very little radium as compared with that of more recent formation. The authors interpret this to mean that the hot water has effected a chemical separation between radium and its parent uranium, carrying off and depositing the former only. In course of time the radium in the travertine decays, and is not replaced by a fresh growth, as in normal radio-active minerals. Since some of the travertine is overlain by glacial boulders, this obviously gives a method of dating the Ice age in this district if the accepted rate of decay of radium be assumed and if we suppose that the material discharged by the spring has been of uniform quality throughout the interval. The figure at which the authors arrive is 20,000 years.

The *Physikalische Zeitschrift* for December 15, 1909, contains a paper by Dr. J. J. Kossonogow, of the University of Kiev, on the application of the ultramicroscope to the study of the phenomena of electrolysis. He finds that when an electrolyte is examined under the ultramicroscope, at the moment the current is switched on there appear in the field of view a number of bright points of light which travel towards the electrodes with velocities of the same order of magnitude as have been found for the ions. The path may be deviated by means of a magnet. When a point reaches an electrode it appears to attach itself and take a crystalline form. None of these appearances is observed in the case of a non-electrolyte, and the author considers he has proved beyond the possibility of doubt that the ultramicroscope provides a powerful means of studying directly the motions of the ions in electrolysis.

A separate copy has reached us of Prof. Zeeman's paper on the degree of completeness of the circular polarisation of magnetically divided lines, which was communicated to the Academy of Science of Amsterdam on October 30, 1909. It will be remembered that a luminous gas in a strong magnetic field gives a spectrum which, when viewed along the lines of the field, consists in the simplest case of two lines, which according to Lorentz's elementary theory of their production should be circularly polarised, one right-, the other left-handed. On examination of lines which normal to the field become triplets, quartets, sextets, and nonets, Prof. Zeeman finds that in each case, whether along the field a line becomes a doublet or a quartet, the lines so produced are circularly polarised, and the degree of circular polarisation found approaches more and more to completeness as the intensity of the light transmitted by the instrument increases. The orbits of the electrons in planes perpendicular to the magnetic field are therefore almost exactly circular.

In an article in *Engineering* for December 31, 1909, on the command of the air and its effect on land warfare, some interesting points are dealt with. We may probably quite disregard the idea of balloons being used to drop bombs into towns for the sake of wantonly destroying private property. There are other and more legitimate ways in which the command of the air may probably be the deciding factor in a war. There is the facility it gives for ascertaining an enemy's disposition and movements, and flying machines may be of great use in war by acting on an enemy's communications. There is no reason why such machines should not start from a ship as well as on land, and, if capable of flying 300 miles, would have a striking distance of 150 miles inland from an enemy's coast. At present it looks as if the aëroplane rather than the navigable balloon would become universal, owing to its being faster, quicker at turning, harder to hit, and very much cheaper.

In an article on latter-day developments of the American locomotive in the *Engineering Magazine* for December, 1909, Mr. H. Keith Trask deplores the fact that American locomotive practice has followed rather than led European practice in matters of design relating to increased efficiency from the standpoint of economy. Thus European designers had long considered the advantages offered by superheated steam before the question was seriously taken up in America. Cheap American fuel was responsible for this neglect, but the recent developments of the compound locomotive have rendered the American designers alive to the benefits resulting from the use of superheated steam. As developed for use on American railroads, the superheater is of two types, the smoke-box and the fire-tube. While both types were originally introduced several years ago, it is only within the past twelve or eighteen months that the American railroad world in general has awakened to their possibilities, and they are being applied to many new engines now building for various roads. The Canadian Pacific was the first road to adopt the fire-tube superheater exclusively, and the Santa Fe, although not the first road to test the smoke-box design, was the pioneer in adopting this device as a standard.

One of the chapters in the recent report of the U.S. Commissioner of Education deals with education in Central Europe. Among much other information of interest in this chapter is a reference to the attempt of Prof. Du Bois-Reymond, in his work on inventions and inventors, to prove that inventive productivity in different countries depends on social factors. General education, density of population, transportation facilities, social organisation, and so on, he maintains, determine this productivity, and despite the participation of working men in State affairs comparatively few patent applications come from them. The result of an inquiry made in 1900 shows that in England 15,300 applications for patents were made, or 37 to every 100,000 of inhabitants, and that the percentage of illiteracy was 3·7. In the United States the corresponding numbers were 22,900, 30, and 6·2, the percentage of illiteracy in this case being of the white population above ten years of age. In Germany the numbers were 14,800, 26, and 0·05. In France, however, only 7020 patents were applied for, or 18 per 100,000 inhabitants, the percentage of illiteracy being 4·6. The numbers in Italy, again, were 1030, 3, and 33·8 per cent. of illiteracy. Race characteristics, in other words, do not predetermine the inventive productivity of a country, nor does the high proportion of literates, but social factors, especially the high status of industry, do determine it. England, the United States, and Germany, the countries having the best developed systems of industry, are the most productive in inventions. Germany alone had, in 1900, 1500 patent applications concerning technical contrivances relating to electricity.

Owing to the death of the late Colonel Bingham, editor of the "Fauna of British India," no volume of the series has been issued for some time. This month, however, Mr. Malcolm Burr's half-volume on the earwigs of British India will appear, which is the first monograph on the Dermaptera which has been published since De Borman's monograph in "Das Tierreich." It will contain a description of a number of new and recently established genera, and will be well illustrated.

OUR ASTRONOMICAL COLUMN.

Halley's Comet, 1909*c*.—Some interesting measures of Halley's comet, made with the micrometer of the Yerkes 40-inch refractor, are published by Prof. Barnard in No. 605 of the *Astronomical Journal*. With this large telescope the comet was quite an easy object, and the measures should be good; but, as Prof. Barnard suggests, the edges of such a nebulous body are not easy to set on.

The measures extend up to November 30, 1909, when the estimated magnitude was about 11·0, and the comet showed a condensation of some $7''$ diameter. The diameter of the whole object was $41''$, and possibly an ill-defined nucleus was seen, but this feature was very doubtful. From September 17 to November 14 the measured diameters, reduced to miles, ranged from 16,400 to 9200 miles, the mean being 12,600 miles, or about $1\frac{1}{2}$ times the earth's diameter.

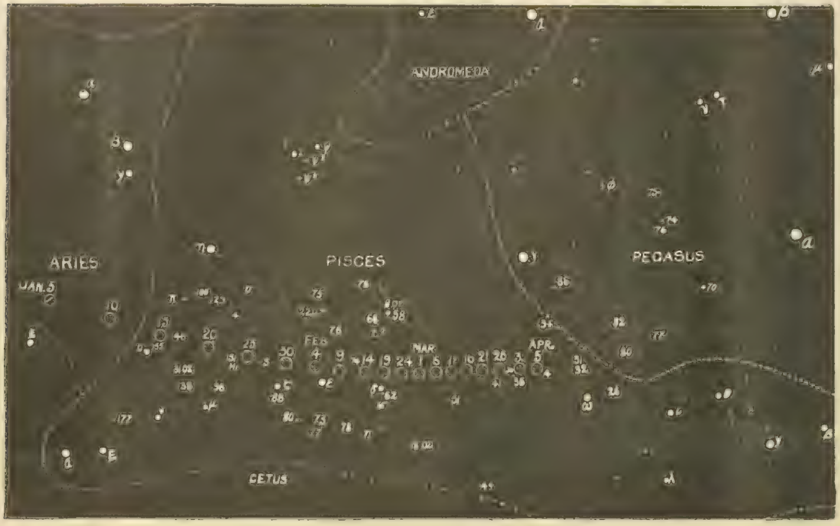
At the December (1909) meeting of the Royal Astronomical Society, reported in No. 418 of the *Observatory*, the Astronomer Royal announced that a photograph secured with the Reynolds reflector at Helwan, on August 24, shows the comet's image; its position agrees within 0·12s. in R.A. and $1{\cdot}7''$ in declination with the position calculated from the Cowell-Crommelin orbit corrected by the Greenwich observations. Messrs. Keeling and Knox-Shaw are to be congratulated heartily upon securing the first known photograph of the comet.

In No. 25 of the *Gazette astronomique*, Signor Pio Emanuelli discusses the probable encounter between the earth and the comet's tail in May next. At 10 a.m. (G.M.T.) on May 18 the comet will pass the descending node of its orbit, whilst the earth will pass the same point ighteen hours later. For an encounter between the tail nd the earth to take place, it is shown to be necessary that the latter should be 22,100,000 km. (13,812,500 miles) long, and that its breadth should be such that it extends, from its axis earthwards, 400,000 km. (250,000 miles).

The accompanying chart shows approximately the nt path of the comet, according to Mr. Crommelin's hemeris, up to April 5.

was re-observed at its returns in 1857, 1870, 1877, 1890, and 1897, but it escaped observation, being unfavourably placed, in 1903.

Mr. Lynn, who gives these particulars in No. 418 of the *Observatory*, also recalls some of the historic occurrences which have coincided with the returns of Halley's comet.



Apparent Path of Halley's Comet, 1910, January 5–April 5.

THE TOTAL SOLAR ECLIPSE OF MAY 8.—From the *Times* of January 5 we learn that Australian observers are already well advanced in their preparations for the observation of the total eclipse of the sun, in Tasmania, on May 8. The conditions of the eclipse—the sun's altitude will be only about 8°—are not sufficiently favourable for the sending of a Government expedition from this country, but the Australian Eclipse Committee is being assisted, by the loan of instruments, &c., by the Joint Eclipse Committee of the Royal, and Royal Astronomical, Societies.

The observations will probably be made from the locality of Port Davey, fourteen hours' journey from Hobart, in difficult country, and a reconnaissance of the district is being arranged for by the Surveyor-General of Tasmania. Messrs. Baracchi, Baldwin, and Merfield are to form the expedition from the Melbourne Observatory, and contingents are expected from the Perth, Sydney, and Adelaide institutions.

Mr. Frank McClean, of Tunbridge Wells, who was so successful at the 1908 eclipse on Flint Island, is about to start for Tasmania, privately, equipped with instruments for photographing the corona and the chromospheric spectrum, &c.

COMETS DUE TO RETURN THIS YEAR.—In addition to Halley's, two other comets are due to pass through perihelion this year. The first is known as Tempel's second periodical comet, discovered in 1873 July 3 at Milan. Its period is about $5\frac{1}{4}$ years, and it was re-observed in 1878, 1894, 1899, and 1904, making its perihelion passage, on last occasion, in November; it should therefore return this coming spring. D'Arrest's comet, discovered in 1851, the second object, and is due to return during the summer of this year. Its period is about $6\frac{1}{2}$ years, and it

OPPOSITIONS OF MARS, AND SIMULTANEOUS DISAPPEARANCES OF JUPITER'S SATELLITES, 1800–1999.—Two useful long-date ephemerides are given by M. Enzo Mora in No. 4379 of the *Astronomische Nachrichten*. The first gives all the dates of the oppositions of Mars between the years 1800 and 1999, the dates of, and the distances and apparent diameters at, perigee, and the relative maximum brilliancy of the planet at each opposition. In the second table are given full particulars of the thirty-six occasions, during the nineteenth and twentieth centuries, on which the four Galilean satellites of Jupiter were, or will be, simultaneously invisible; the next occasion is not until October 21, 1913.

A BRILLIANT FIREBALL.—In No. 418 of the *Observatory* Mr. Denning describes the path of a brilliant fireball which was observed at Harrow and at Bournemouth on November 7, 1909. The true path of this meteor was over Tours and Angers, in France, at a height of from fifty-nine to forty-five miles, and, on the assumption that its radiant was near *e* Tauri, at 58°, +9°, the motion was due east to west. Observations from France, where the meteor must have appeared very bright, are desirable.

ANCIENT IDEAS OF THE PHYSICAL WORLD.—In an article which appears in No. 72 of *La Revue des Idées* (December 15, 1909), M. Leon Jaloustre gives an account of the ideas held by the ancients, at different epochs, anent the physical constitution of the universe. Most of these ideas were, of course, connected with astronomy, and the hypotheses of philosophers from Plato onwards are discussed in a very interesting manner.

MINOR PLANETS.—In *Astronomische Nachrichten*, No. 4380, Dr. Neugebauer continues the list giving the adopted numbers and the orbital elements of minor planets. The present table includes Nos. (661) to (673) inclusive, which were discovered in 1908.

MARINE BIOLOGY AT PORT ERIN.

THE annual report of the Marine Biological Station at Port Erin, Isle of Man, being the twenty-third annual report of the Liverpool Marine Biology Committee, has just been published, and it may be of interest to refer briefly to some of the features of a successful year's work. The station appears to have been more active than ever this last year, and the record of work indicates that researches of a most varied nature have been carried out.

FIG. 1.—The Biological Station at Port Erin

The adjoining fish hatchery (the expenses of which are met by the Isle of Man Fishery Board) has been employed, as usual, in the hatching of plaice eggs, and a total of 7,124,500 larvæ were liberated in the open sea. Some of the eggs have been used for experimental purposes, and a series of extremely good photographs, taken by Dr. F. Ward, and illustrating various stages of the larvæ from the time of hatching until metamorphosis had begun, are included in the report. The number of workers who occupied tables in the laboratory is forty, of whom twenty were senior students of the Liverpool University attending an Easter class in marine biology, which has now become an annual fixture. As a matter of fact, the station is usually crowded during the Easter vacation, and a visitor would be struck immediately by the number of people taking advantage of the laboratory, and by the economical way in which the work is carried out. More than one foreign professor of zoology has been surprised, on learning the finances of the Biological Station, that the place could be kept going with active workers there at all, for it must be remembered that this is not a laboratory subsidised by Government or county council, but depending for the main part of its income upon the voluntary contributions of those interested in the work.

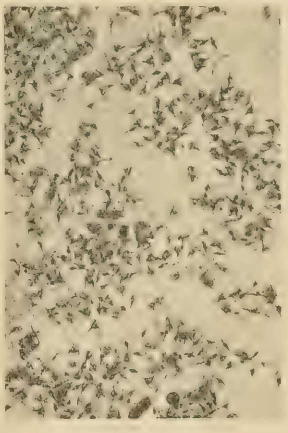


FIG. 2.—Plankton consisting mainly of *Ceratium tripos*.

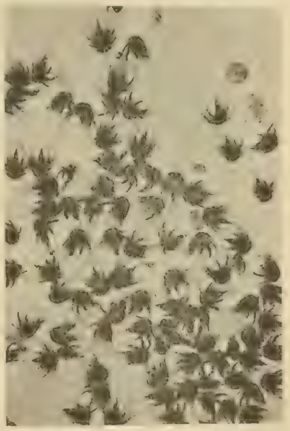

FIG. 3.—Plankton catch consisting almost entirely of *Balanus nauplii*.

In addition to the report of the curator (Mr. Chadwick) are minor reports on some of the research work, including statements of Mr. W. J. Dakin's work on the sense organs of Mollusca, Mr. F. H. Gravely's studies on the polychæte larvæ, and Dr. Roaf's researches on the digestive processes in marine Invertebrata—histological, biochemical, and faunistic work being thus represented. An article by Prof. W. A. Herdman on "Our Food from the Sea" completes the report, and alludes to the scope of the quantitative plankton investigation, which has been one of the features of Port Erin work. The article is illustrated by some photographs of practically pure plankton catches, of which two are reproduced here (Figs. 2 and 3).

No doubt many scientific workers in other branches of zoology who have not considered this quantitative plankton work in detail still hold more or less to Haeckel's view—that time is being lost by using methods which are inaccurate, based upon principles which are impossible. It may be useful, therefore, to consider some of these points here, for a report of this kind brings us up against the question of the practicability and value of quantitative plankton research. During the last few years the number of workers studying the plankton of fresh and salt water has greatly increased, and some of the most remarkable problems in marine biology have been shown to be bound up in plankton questions. I might refer, in the first place, to Pütter, who but a short time ago propounded certain startling theories concerning the food of marine organisms. According to this author the planktonic organisms are insufficient to provide for the wants of many marine animals which can only obtain their food from filtered sea water, and he asserts that the latter is in itself a nutrient fluid.

Many facts, both biological and chemical, have been brought forward against these theories, but, whether correct or not, Pütter has shown the need of further research and the importance of the problem of animal metabolism in the sea. The actual food requirements of the animals must be determined by physiological and biochemical methods, and quantitative plankton methods alone will show whether the plankton can supply the demands made by the physiologist. The total plankton present at any time is the result of a series of processes—productive and destructive—and it is important to know how the volume or quantity varies.

No qualitative work will show the seasonal, or even daily, variation in the volume of the plankton, though it may indicate the specific change. The interest in such problems is immediately aroused when catches with a certain net, after averaging a few cubic centimetres in volume, suddenly rise to 40 cubic centimetres, remain there for a period, and then as suddenly fall to about 1 c.c. or 2 c.c. for the summer season, and this is a characteristic annual change observed in the Irish and Baltic Seas. What determines these changes in volume? When do they occur? Is there a relation between the times of maxima of different groups of plants or animals? We can hardly look to qualitative plankton work for the answers, and it has been the quantitative methods that have mapped out the spring maxima of diatoms and dino-flagellates, and, in opposition to qualitative results, have shown how in temperate and arctic regions the plankton is greater in volume than in the tropics.

Again, in order to show whether the changes in the plankton are due to inherent qualities in the organisms, to external influential hydrographical conditions, or to both, a combination of hydrographic and planktonic work is required. It is, I think, obvious that there are many problems awaiting solution, and our choice is limited to the alternative of either leaving them alone or adopting quantitative methods.

It has been said that the latter are inaccurate. Of course they are, to a certain extent, but unfortunately we have no better at our disposal, and have considered it better to use the most accurate methods possible, and to remember the error when drawing our conclusions, than to leave the whole question alone. It is significant that all the objections, backed by scientific evidence, which have been brought against the quantitative methods have come from investigators using these methods. It is obvious, therefore, that their eyes are open to the defects of the methods and the limits of the apparatus used. In this respect may be mentioned the work of Lohmann and Kofoid on the catching power of the nets (Fig. 4), and of Herdman in regard to the variations in uniformity in the distribution of the plankton, which question was the first to be considered in the Port Erin work. I cannot do better than quote certain lines from the article in the report referred to:—"With the object of formulating such views as to the nature of the Plankton at any particular time, and as to the changes, both diurnal and seasonal, and the determining factors of such changes, we must endeavour to make quantitative catches as accurately and as frequently as possible, so that our samples may be as nearly representative and as nearly comparable one with another as the difficult conditions will admit. These catches should be made with standard nets, should be preserved and measured according to a uniform system, and may then be compared in bulk; but, in addition, the more important organisms should be counted approximately, and the results in round numbers may be used in comparing catches or tracing changes; but such figures should not be made the basis of calculations as to the total numbers of such organisms in the oceans." The last sentence cannot be too strongly emphasised; the quantitative method is *not* used with the object of determining the number of diatoms in the Irish Sea, and *comparisons* of figures obtained in a uniform way should be the feature of the system.

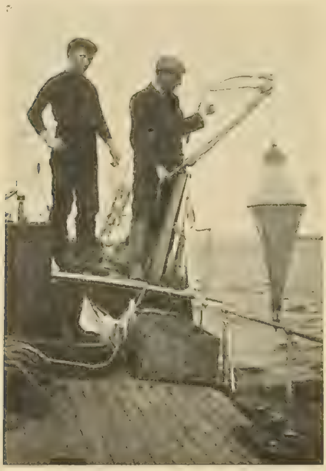

FIG. 4.—The Closing Petersen-Hensen Net going down open.

It would be of great value if some system could be arranged so that plankton catches made in a uniform manner could be taken in different parts of the Irish Sea and St. George's Channel simultaneously. This would greatly help in mapping out the distribution of the plankton and tracing the course of the maxima. For example, in July last, after weeks' of catches containing a normal and small number of various copepoda, echinoderm larvæ, &c., the nets one day were found to contain large masses of *Calanus helgolandicus*. The catches were almost pure, and, in fact, practically useless for the echinoderm larvæ that were wanted. This condition of affairs lasted from two to three days, and then the Calanus swarm disappeared as mysteriously as it came. Systematic and simultaneous catches in the Irish Sea would have shown over what area this Calanus swarm extended, and perhaps whence it came.

W. J. DAKIN.

PRIZES PROPOSED BY THE PARIS ACADEMY OF SCIENCES FOR 1911.

GEOMETRY.—The Francœur prize (1000 francs), for discoveries or works useful to the progress of pure or applied mathematics; the Bordin prize (3000 francs), for improving at an important point the theory of triple systems of orthogonal surfaces; the Poncelet prize (2000 francs), for work in applied mathematics.

Mechanics.—A Montyon prize (700 francs), for the invention or improvement of instruments useful to the progress of agriculture, the mechanical arts or sciences; the Vaillant prize (4000 francs); the subject for 1909, postponed to 1911, is to improve the application of the principles of the dynamics of fluids to the theory of the helix, and the question proposed for 1911 is to perfect at some point the study of the motion of an ellipsoid in an indefinite liquid, having regard to the viscosity of the liquid.

Navigation.—The extraordinary prize of 6000 francs, for work tending to increase the efficiency of the French naval forces; the Plumey prize (4000 francs), for improvements in steam engines or for any other invention which would contribute to the progress of steam navigation.

Astronomy.—The Lalande prize (540 francs), for the most interesting observation, memoir, or work useful to the progress of astronomy; the Valz prize (460 francs), for the most interesting astronomical observation made during the current year; the G. de Pontécoulant prize (700 francs); the Damoiseau prize (2000 francs), subject postponed from 1909, the theory of the planet Eros based on known observations, and for 1911, to perfect the "Tables de Jupiter" of Le Verrier.

Geography.—The Tchihatchef prize (3000 francs), for a recompense or encouragement for exploration of the unexplored or partially explored portions of Asia; the Gay prize (1500 francs), for the study of a French African colony from the geological point of view (Algeria and Tunis excepted).

Physics.—The Hébert prize (1000 francs), for a discovery in applied electricity; the Hughes prize (2500 francs), for a discovery or work contributing to the progress of physics; the Gaston Planté prize (3000 francs), for an important invention, discovery, or work in the field of electricity.

Chemistry.—The Jecker prize (10,000 francs), for work in organic chemistry; the Cahours prize (3000 francs), for the assistance of young chemists already known by their original chemical researches; Montyon prizes (unhealthy trades) (2500 francs and a mention of 1500 francs), for a discovery of a means of rendering an art or trade less unhealthy.

Mineralogy and Geology.—The Delesse prize (1400 francs); the Joseph Labbé prize (1000 francs), for geological works or researches leading to effective development of the mining wealth of France, its colonies or protectorates; Fontannes prize (2000 francs), to the author of the best palæontological publication.

Botany.—The Desmazières prize (1600 francs), for a publication on cryptogams; the Montagne prize (1500 francs), for important works bearing on the anatomy, physiology, development, or description of the lower cryptogams; the de Coincy prize (900 francs), for a work on phanerogams; the Thoré prize (200 francs), for the best work on the cellular cryptogams of Europe.

Anatomy and Zoology.—The Savigny prize (1500 francs), for the assistance of young travelling zoologists, not in receipt of Government assistance, who occupy themselves more especially with the invertebrates of Egypt and Syria; Grand prize of the physical sciences (3000 francs), for the morphogenic study of the characters of adaptation to tree life in the vertebrates; the Cuvier prize (1500 francs), for a work on zoological palæontology, comparative anatomy, or zoology.

Medicine and Surgery.—Montyon prize (2500 francs, mention of 1500 francs); the Barbier prize (2000 francs), for a valuable discovery in surgical, medical, or pharmaceutical science, or in botany in its relation to medicine; the Bréant prize (100,000 francs), for discovering a cure for Asiatic cholera, or by discovering and removing its cause; the Godard prize (1000 francs), for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; the Baron Larrey prize (750 francs), for an army or navy surgeon or physician for the best work dealing with the subject of military medicine, surgery, or hygiene; the Bellion prize (1400 francs); the Mège prize (10,000 francs); the Chaussier prize (10,000 francs), for the best book or memoir on practical or forensic medicine.

Physiology.—A Montyon prize (750 francs), for experimental physiology; the Philipeaux prize (900 francs); the Lallemand prize (1800 francs), for the encouragement of work on the nervous system; the Pourat prize (1000 francs), for a memoir on the origin of the antiferments (postponed from 1909), and (1911) for a memoir on the influence of the mineral elements, especially of calcium, on the activity of the digestive diastases.

Statistics.—A Montyon prize (1000 francs, a mention of 500 francs).

History of Science.—The Binoux prize (2000 francs).

General Prizes.—The Arago, Lavoisier, and Berthelot medals; the Gegner prize (3800 francs); the Lannelongue prize (2000 francs); the Trémont prize (1100 francs); the Wilde prize (one of 4000 francs or two of 2000 francs), for discoveries in astronomy, physics, chemistry, mineralogy, geology, or experimental mechanics; the Lonchampt prize (4000 francs); the Saintour prize (3000 francs), for work in mathematics; the Victor Raulin prize (1500 francs), for assisting the publication of works in geology and palæontology; the prize founded by Mme. la Marquise de Laplace; the Félix Rivot prize (2500 francs); the Pierson-Perrin prize (5000 francs), for a discovery in mechanics or physics; the Serres prize (7500 francs), for works on general embryology applied to physiology and medicine; the Jean Reynaud prize (10,000 francs), for an original scientific work; the Petit d'Ormoy prize (two prizes of 10,000 francs), one for work in pure and applied mathematics, and one for natural science; the Baron de Joest prize (2000 francs).

LONDON COUNTY COUNCIL CONFERENCE OF TEACHERS.

SIX addresses were given from the chair and twenty papers were read at the meetings held on January 6, 7, and 8 at the Birkbeck College. As a rule, the gatherings were large, and the papers read were of considerable importance. We understand that the London County Council will publish and distribute a complete report with the same liberality as in former years.

The subjects of the papers were classed under the headings:—(1) organisation of higher schools; (2) training of engineers; (3) teaching of number; (4) teaching of domestic economy; (5) methods of teaching in schools for the mentally defective; (6) educational experiments in schools. With so varied a programme it is not easy to point to any single idea as dominant in the papers or in the discussions which followed. Nevertheless, it is safe to say that there was a continued endeavour, consciously in some cases and unconsciously in the remainder, to bring the work within the school walls into closer relation with the present and future activities of the pupils in their daily lives.

The main impression produced by the conference as a whole—an impression which could hardly escape the notice of any reflective observer—was that the London education authority is acting with wise foresight in encouraging initiative and individuality among its teachers. One cannot, of course, assume that such encouragement is given in every school simply on the evidence of these meetings, but there is no doubt that men of originality and proved competence are encouraged and helped to put into practice new ideas and new methods, and that this is true for the older as well as the newer subjects of the curriculum. It is not easy to overrate the importance of the attitude of the London Education Committee and its official advisers with regard to this treatment of the teacher. Whether we approve or not, for good or for ill, the growing municipalisation of education in this country is an irresistible fact.

That the administration should be municipalised is probably a benefit; we may agree with Mr. Cyril Cobb (who opened the conference) in his view that the union of education with other municipal work was good, both for education and the other municipal departments which were brought into touch with it. The danger—and it is a grave one—is that the teachers may become bureaucratised—that they may sacrifice the finer elements of professional spirit to the attainment of smooth and trustworthy working as components of the municipal machine. If English schools are to continue to deserve their reputation for training character it can only be by retaining the requisite spirit in the teachers. From these considerations we may regard the tone of these conferences as promising well for the future of London education. With thankfulness we recognise that the London County Council is anticipating the dangers which are liable to accrue from the very efficiency of its system, and is inhibiting their growth by promoting the development of initiative and of independent professional criticism among the teachers in the London service.

Organisation of Higher Schools.

Turning to the headings given above, under (1) Mrs. Millington discussed the aims of the new Central Schools for Girls, for which the age of entry is eleven to twelve and of leaving fifteen to sixteen. Girls needed both fitness to take charge of a home and fitness for commercial or industrial employment. Training for home-making should be given to all girls alike; for this purpose a small house, a day-nursery, and a small garden should be attached to the schools. Poetry, music, and one foreign language were among the essentials. Mr. H. J. Spenser, headmaster of University College School, read a paper on the organisation of a large secondary school, in the course of which he said that, as compared with other nations, we suffered from lack of expert knowledge in our rulers. Abroad, the men who controlled national systems were men who had spent most of their lives in teaching. We pay a heavy price for amateur government. The greatest national need to-day is the need for efficiency in the secondary schools.

Training of Engineers.

The discussion on the training of engineers took place under the presidency of Sir William White, who advocated a preliminary practical training interposed between the secondary school and the technical college. It was during that period that the boy learned most from the workman, and in Germany they had gone back to that system. After Dr. Walmsley had described the "sandwich" system of training as practised by engineering students of the Northampton Polytechnic Institute at Clerkenwell, a paper was read by Prof. D. S. Capper, in which the author reviewed the whole subject. He divided an engineer's training into (1) school training; (2) scientific training; (3) technical training; (4) subsequent training. As regards (1), he deprecated specialisation, advocated freehand and mechanical drawing, and limited the usefulness of school workshops to teaching a boy to use his tools, to think in the solid and to realise methods of simple construction.

Study of literature and history should balance the work in mathematics, physics, and chemistry. Modern methods of teaching mathematics in schools had produced a great improvement. After school, the factory or office training should extend over two or three years. Should a year of it be interposed between school and college, and the remainder be completed after college? Or should the summer of each year be spent in the factory and the winter in college? Twenty years' experience had shown him that the answer depended on the individual temperament of the student. The college course should lead to a science degree, and the technical diploma should be granted, not by the university, but by a professional body qualified to judge technical training. This training must be carried out on its "clinical" side on a commercial scale and amid commercial surroundings. With reference to the London matriculation, he pleaded for a simplification of the "English" paper and for the introduction of trigonometry in the syllabus for elementary mathematics. At whatever branch of engineering the students were aiming, they should acquire some knowledge of machinery and machine processes, and also some familiarity with the applications of electricity—for engineering practice, not for passing an examination. Specialised professional subjects, *e.g.* bridge building, should be treated at the post-graduate stage.

Domestic Economy.

Mr. J. Wilson (Battersea Polytechnic) delivered an address on the correlation between the teaching of domestic economy and experimental science. The practical problems are how to link the chemistry and physics to the domestic subjects, and how to teach the latter, so far as possible, as applied science. Should the experimental science and the domestic subjects be fused together into one subject? After an experience of ten years at Battersea, the lecturer gave it as his opinion that they should remain two distinct but correlated branches of study. At present the proper teaching of the science subjects on the one hand, and the domestic subjects on the other, demands a specialist mistress for each group. There must be frequent consultation between the two teachers to ensure proper coordination. The principles to be followed were illustrated by detailed discussion of the following typical course for a girls' secondary school (some nature-study should precede the course):—

	Science	Household Work
First year.	Physical measurements. Heat. Chemistry of air.	Needlework.
Second year.	Water and Solution. Acids, alkalis, &c. Chalk, lime. Derivatives of common acids.	Cleaning materials. Elementary principles of cookery.
Third year.	Chemical change; outlines of theory. Flame, washing soda, borax, sugar, alcohol, vinegar, oils and fats, soap.	More advanced cookery and needlework.
Fourth year.	Classification of food-stuffs. Starch, flour and cereals. Milk, butter, cheese, eggs. Meat, meat extracts. Vegetables. Tea, coffee, cocoa.	Cookery; potatoes, rice, bread, cakes, puddings. Soup; cooking meat.
Fifth year.	Digestion: dietetics, dietary scales. Heat values. Elementary bacteriology (air, water, milk, dust). Preservation of foods. Laundry; textile fibres; bleaching; examination of soaps; dry cleaning.	Experimental cookery (an adaptation of "research in household processes.") Laundry work.

Generally speaking, the girls feel that the work is of direct value to them, and the course proves to be as truly educational as the older courses of systematic chemistry and physics, although the problems studied are much more complex. With the present regulations for matriculation, girls who enter for this examination cannot take the fourth or fifth year's course. Mr. Wilson suggested that the London University and the Joint Scholarships Board should add a suitable syllabus which would allow candidates to follow such a course as the one outlined.

Sir Lauder Brunton, who presided, and the Hon. Mrs. Bertrand Russell, dealt with the social aspect of the subject, and it was pointed out that the comfort, health, and sobriety of the nation depended to a great extent on efficient and widespread teaching of domestic economy.

Other Subjects.

The initiated are aware that the teaching of number is of far greater importance than is generally supposed, and will learn without surprise that a whole session was devoted to that topic. Mr. T. Raymont (Goldsmiths' College) opened with an exposition of fundamental principles. The fifth meeting was devoted to problems connected with mentally defective children, and there was a small exhibition of work accomplished, which served to illustrate the methods of teaching in some of the council's special schools.

The final meeting was in many respects the most important and encouraging of the series organised by Dr. Kimmins. Under the title "Educational Experiments in Schools" was given the clearest evidence of the abilities of the teachers and of the opportunities afforded them to develop their ideas. Mr. E. White, handicraft instructor at Essendine Road, gave a lucid account of the manner in which the work of his handicraft centre had been coordinated with that of the schools connected therewith. A sound start was made by bringing the class-teachers into closer relation with the instructor. The council's inspectors and H.M. inspectors gave help, with the result that arithmetic, nature-study, science, and in a lesser degree composition, geography, and history, were all benefited by the connection established between these subjects and the manual work. Mr. J. S. Fowler showed how to treat "weather study" so that its real importance and interest were grasped by boys, and Mr. A. Beaver dealt in a practical way with local history. Miss C. von Wyss gave much-needed advice upon the care of animals in schools. Teachers who wish to keep their furred, feathered, or finned pets in good health should read this paper in the coming report. Incidentally, they will, it is to be hoped, both imbibe themselves and infuse into their pupils that spirit which prompts "courtesy to tadpoles."

G. F. D.

ELECTRIC VALVES.

NOW that the use of higher voltages for bulk supply is becoming more general in this country, the question of protection of electrical plant against damage due to resonance surges in underground lines and atmospheric disturbances as well as in overhead lines—which for commercial reasons are likely to become more common in the near future—is one that electrical engineers should turn their attention to at the present time.

Where trouble has already occurred in central stations it has generally been put down to faulty design or bad insulation of the machines. There is no doubt, however, that the damage is caused very often by the setting up—owing to a short circuit or the sudden action of the automatic fuse—of a serious rise of potential, which is stored in the windings of the alternator, and can only flow off through the capacity of the transformer or by perforating the insulation. Such voltages rapidly deteriorate the insulation of sunk windings, and so it becomes necessary to find some means of overcoming this difficulty. Two such pieces of apparatus are now available, and may be used in conjunction with each other or separately, according to the conditions controlling the line, area of distribution, capacity of plant, &c., and are known as the "electric valve" and "Moscicki condenser."

The electric valve consists of a number of spark-gaps arranged as follows. The first spark-gap is placed in series with a sufficiently high resistance, so as to avoid high-frequency oscillations, and the remaining spark-gaps are indirectly connected to earth through small condensers, the last spark electrode being connected direct to earth. The spark-gaps are formed between the edges of sharp round discs of non-arcing metal insulated from each other and from the earth connection. The capacity required is obtained by these discs and a central rod which is connected to earth, and also acts as a support for the discs which are insulated from it. The resistance in series with these discs is a metallic one, and obviates the trouble usually due to high resistances of graphite or carborundum.

The first spark-gap is adjustable, and is enclosed in a glass cylinder. Six or more sets of spark-gaps are connected in parallel—each through a high-tension fuse—to a common disc, which acts as one pole, while the cast-iron base to which the columns are bolted acts as the other pole. The columns are protected from dust and damage by a glass cylinder, which rests on rubber pads on the cast-iron base, and is protected on top by an insulated cover.

The characteristics of the electric valve may be summed up as follows:—(1) absolute prevention of high-frequency currents; (2) unlimited capacity for dealing with any energy; (3) the adjustable spark-gaps being enclosed in glass cylinders, there is no likelihood of dust getting between the knobs and causing premature action of the apparatus; (4) the automatic extinction of the arc; (5) erection or dismounting very rapid.

The Moscicki condenser resembles an extremely long Leyden jar, with the difference that the neck of the jar—where the coatings end—is considerably thickened. The coatings are produced by a chemical silvering process, and a heavy deposit on both the inside and outside of the jar is obtained, which is further strengthened and protected by a copper deposit. The jars are then mounted in a tin or brass tube, on the top of which a high-tension insulator is arranged, and carries the contact connected to the inner coating. The outer coating is connected to the metal tube, and the intermediate space is filled with a mixture of glycerin and water. It is then hermetically sealed, and consequently the condenser can be used in any position. Glass is used for the dielectric, owing to its great dielectric capacity and uniformity.

The usual type of condenser as used for line protection consists of a number of tubes, as described above, mounted on a wrought-iron frame, and the inner coatings are connected in parallel through high-tension fuses to a common terminal, to which the line is connected. The outer coatings are connected to the tin or brass tubes, and connected to earth by means of the framework, which is so arranged that each tube can be easily replaced or removed when it is necessary.

The design and action of both the electric valve and the Moscicki condensers are clearly explained in a pamphlet issued by Messrs. Isenthal and Co., of 85 Mortimer Street, W., who have acquired the patent rights for both these forms of apparatus for this country and the colonies.

EDUCATION DURING ADOLESCENCE.[1]

FOR the vast majority of English boys and girls, our system of national education is a torso. It ends too soon. It is a trunk without a head. How to remedy this defect with practical wisdom, without expenditure so immense as to provoke reaction, and with the convinced cooperation of enlightened employers of labour, and of all parents who unselfishly desire to further the best interests of their children, is becoming one of the pressing questions of the day.

Out of some 1,300,000 boys and girls in England and Wales who are between twelve and fourteen years of age there are (to the best of our knowledge) about 211,000 (in addition to partial exemption scholars) who have already obtained exemption from attendance at school, and are receiving no further systematic education. Out of the two million young people in England and Wales who have passed their fourteenth birthday, but are still under seventeen years of age, only one in four (so far as our knowledge goes) receives on week days any continued education. "The result" (I quote the finding of the Consultative Committee) "is a tragic waste of early promise. Through lack of technical training, hundreds of thousands of young people fail to acquire the self-adaptiveness and dexterity in handicraft which would enable them to rise to the higher levels of skilled employment. Through lack of suitable physical training, their bodily powers are insufficiently developed, and their self-control impaired. Through lack of general training, their mental outlook remains narrow, their sympathies uncultivated, their capacity for cooperation in civic welfare stunted and untrained. In the meantime, modern industry, in some of its developments, is exploiting boy and girl labour during the years of adolescence. An increasing number of 'blind-alley' employments tempt boys and girls, at the close of their day-school course, by relatively high rates of wages which furnish opportunities of too early independence, but give no promise of permanent occupation and weaken the ties of parental control."

The present state of things is not only intellectually and economically wasteful, but often morally mischievous. City life enhances the danger. Unskilled, or relatively unskilled, employment at thirteen, with good money, tempts a boy (and an increasing number of girls) like a baited trap. A lad is drawn into a way of life which leaves him at sixteen or seventeen without a trade to his fingers, and with the habit of steady learning clean gone out of his head. The years between thirteen and sixteen or seventeen are the years of educational leakage. We are like people who have laid down a costly system of water supply, but have left a badly leaking pipe just behind the tap. In order that our system of national education for the masses of the people may bear better fruit in personal skill and in civic value, the time has come for us to secure a better foundation in the elementary day schools and the continuance of wise educational attendance during the years of adolescence.

Differ as we may in judgment as to the legislative treatment of the problem, we find, I think, but little disagreement among ourselves in educational aim. Do we not virtually concur in thinking that all boys and girls ought to receive, during the years of adolescence, some form of continued education which will develop their physique, widen their mental outlook, cultivate their sympathies, prepare them for the responsibilities of parenthood, equip them for trustworthy efficiency in the occupation by which they will earn their livelihood, and fit them for the duties of citizenship? If this is to be done, it will be necessary to mortise the work of the day and evening technical classes into the work of the elementary day schools. We need in the latter more training of the hand and of the constructive powers, not with any prematurely technical purpose, but as a necessary factor in brain development and in a liberal education. This will not be possible unless we have smaller classes in the elementary day schools and unless the course of training for teachers can be so prolonged as to permit training in educational handwork to be included in their course of professional preparation without congestion of studies, without overpressure of mind, without encroachment upon the indispensable liberal education, and without undue curtailment of that mental leisure which is needed for all healthy growth of interest, originality, and purpose. Nor do we conceive of the technical class, whether day or evening, as purely utilitarian or technological. Direct bearing upon subsequent employment or occupation it must have. But inseparable from its true educational influence is careful regard for the training of the body, for the cultivation of the sympathies and of the imagination by the love of literature, by music and by art, for an opening of the mind to the significance of civic responsibility, and also for those influences (often most powerful when least expressed in words) which help in forming a purposeful, steadfast, and disinterested character.

It is because the people's high schools in Denmark have not only aspired to these aims, but have largely achieved them, that they have raised the level of culture in the whole nation and have indirectly, and, as it were, in by-product, enhanced the economic welfare of the people. Nor should it be forgotten that the Danish high schools do not receive children during the years immediately following the day-school course, but are confined to pupils above sixteen years of age. For this reason, the Danish high schools are not at present fully grappling with the problem of how best to continue the education of urban children; but the record and success of these schools may well make us hesitate before embracing the conclusion that, for children in the agricultural districts, attendance at a continuation class between fourteen and sixteen is the only, or indeed the best, way of securing the kind of further education most fitted to their needs.

---

[1] From a paper on "The Relation of Elementary Schools to Technical Schools—Day and Evening," read at the North of England Education Conference, Leeds, on January 7, by Prof. M. E. Sadler.

Many of the statements now current as to the universality of compulsory attendance at continuation schools in different parts of Germany seem to me unintentionally misleading. After persistent efforts, and with the help of some of the best informed of German educators, I have failed to obtain any comprehensive statistical statement showing the number of boys and girls between fourteen and seventeen years of age in different parts of the German Empire who are actually attending continuation schools. Where I have been able to test such figures as are published, I have been drawn to the conclusion that the enforcement of compulsion, even in those parts of Germany where compulsion is statutory, is less general than the wording of the statutes would lead us to expect. The whole subject calls for closer investigation. There is some reason to think that, even in the progressive parts of Germany (and there are large regions in which education is the reverse of progressive), the problem of securing continued education for the majority of girls, and also for those boys who are not intending to enter a skilled trade, is still far from having been effectively solved. We in England have indeed much to learn from Germany and from some of the cantons of Switzerland, but it is right to remember that, for historical reasons which are far from discreditable to us, we have approached the problem from the point of view of the individual rather than from the point of view of the State. I can find no country in which the voluntary attendance at evening classes is so large in proportion to the adult population as it is in England and Wales. I would venture to urge that our task is so to use the collective power of the State as to stimulate, but not to supersede, the energy and forethought of the individual. Bureaucratic collectivism in education seems to me as false an ideal as, at the opposite extreme, is chaotic and plunging individualism. We need a synthesis between the individual energy of the pupil, the responsibility of the parent, the responsibility of the employer, and the watchful supervision, the financial aid, and the uplifting public purpose of the local authority and of the State. Nor, in this matter of continued education, should we allow ourselves to attach too much importance to academic standards of attainment or of theoretical knowledge. Much of the best education in the world is remote from the class-room.

In England, the difficulties which we find in the way of bringing the elementary schools into closer and more fruitful relation to a stimulating kind of further and largely technical education are partly psychological, partly administrative, partly economic.

A great number of English employers and foremen are lacking in insight into the true meaning and value of education, and also often fail to discharge their moral responsibilities for the further education of the young people in their employment or under their care. Nothing strikes me so much in comparing a German industrial city with an English as the keener interest on the part of the mass of German employers in educational questions, and especially in the educational aspect of the daily duties of the workshop. We in England are apt to forget that education is really an aspect of life, and that every skilled adult may find one of his keenest pleasures in imparting a right attitude of mind and a sense of skill and finish to the young people growing up under his care. These things are partly traditional in a nation, and the unbroken tradition of skilled workmanship which has survived from the Middle Ages to the present day in many of the older German cities is one cause of the German attitude of mind towards industrial and technical training. With us the industrial revolution, which introduced the factory system (great as that achievement was from many points of view), snapped an ancient tradition (which already was half dead) and purposely re-started industry in new places where the old tradition had never grown. The first step towards the diffusion of a deeper insight into the value of education is the extension of a liberal, non-pedantic, non-examination-ridden, secondary education accessible, not only to the employing class, but to those who will rise to be foremen and thus hold responsible, though subordinate, posts in industry and commerce. When a man has himself had at school an education which has affected his whole life, he is more ready to understand the importance of securing a similarly suitable education for other people.

It is idle to deny that a comprehensive system of continued education during adolescence (the kind of system which the country really needs and without which much of its present expenditure runs wastefully into the sand) will be a very costly thing to provide and maintain. On the Consultative Committee we tried to form an honest estimate of the cost. We came to the conclusion that a system of compulsory attendance at continuation schools of all young persons between fourteen and seventeen years of age would, if universally applied in a satisfactory manner, involve for maintenance alone an additional annual expenditure of two and a half million pounds. For my own part, I believe that if the work in continuation schools were made (as it should be made) thoroughly practical, the cost would be considerably greater.

Every month given to the further study of the subject which we are met to discuss impresses upon us more deeply the range and social complexity of the issues which necessarily arise, in this country and elsewhere, whenever the problem of continuation schools is seriously approached. The better adaptation of technical schools, day and evening, to the public elementary-school system involves something far beyond skilful administration on the part of the local authorities, and is on a quite different plane of difficulty from that of previous proposals for the raising of the school age. It would be misleading to discuss the subject with our attention confined to narrow technicalities or administrative details, necessary as those are to the right solution of our difficulties. On the whole, as it seems to me, we have just reason for encouragement as to the future. There are many signs that the nation is approaching the problem in the right attitude of mind and with willingness fairly to consider temperately stated arguments for reform. The growth of this right attitude of mind is much more important than hurried legislation, which, indeed, if precipitately forced on to the Statute Book, would retard rather than hasten our advance. English opinion ripens slowly, but I believe that ultimately it will regard as a social necessity the continued education of young people during adolescence under conditions which will protect them from overwork of body and mind. In the meantime, the Scottish experiment is full of significance for us. The foundations of an effective continuation-school system must be laid through a change in the conditions of attendance and study in the elementary schools. Our primary need is a raising of the normal age for exemption from day-school attendance to the limit adopted in Scotland since 1901. Further, is not the time ripe for imposing on every local authority the statutory duty of making suitable provision of continuation classes for the further education of young persons resident in their district from the time they leave the day school up to their seventeenth birthday, and of keeping a register of all such young persons with a record of their occupations? In order that this duty may be rightly discharged, it appears to me indispensable that the Parliamentary grant in aid of continuation schools should be materially enlarged. Without such aid the poorer districts in town and country will not be able to support the expense of providing instruction sufficiently practical or teachers adequate to the task of imparting it. In this particular grade of education the schools must necessarily compete with industry and with commerce for the services of those who are really competent to teach what the pupils will most require to learn.

With the growth of public confidence in their fair-mindedness and educational insight, the local authorities will acquire that moral authority which will alone enable them to exercise the power, almost certain in the end to be entrusted to them by statute, of prescribing the limit of hours of work which no young person under the age of seventeen may exceed in any day or week in employment and systematic education combined; but in order to secure in an effective way physical, technical, and civic training for all young people during the years immediately following the close of the day-school course, two other statutory changes seem to me to be necessary. First, it should be lawful for the education authority of any county or county borough to make bye-laws (subject to confirmation by the Board of Education) for requiring the attendance at continuation classes up to any age not exceeding seventeen years of any young persons resident or working in their district and not otherwise receiving a suitable education. Secondly, Parliament should make it the statutory duty of every employer of any young person under seventeen years of age (*a*) to enable him or her to attend continuation classes for such period of time and at such hours as may be required by the bye-laws of the local education authority of the district in which such young person either works or resides, and (*b*) to supply the names of all such young persons to the local authority on its demand; and, in order to secure the regular attendance of pupils at technical and other continuation classes in areas where such attendance is made compulsory by bye-law, all employers in such trades or parts of the district as the bye-law may specify should be forbidden, under penalty, to employ any young person under seventeen years of age who fails periodically to produce a card attesting his or her attendance at continuation classes in conformity with the terms of the local bye-law.

These are the central and fundamental recommendations unanimously made by the Consultative Committee of the Board of Education. They are so designed as to stimulate individual energy within the necessary framework of administrative unity.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A POST-GRADUATE course of seven lectures on "Photo-electricity" will be given at King's College (University of London) during the Lent term, by Dr. H. Stanley Allen, on Wednesdays, at 5 p.m., beginning on January 19. These lectures are open without fee to internal students of the University on production of a card of admission from their college.

IT is stated in *Science* that Mr. Henry Phipps, of New York, founder of the Phipps Institute in Philadelphia, has presented to the University of Pennsylvania the sum of 100,000*l*., to be used in the campaign against tuberculosis. Six years ago Mr. Phipps founded the Phipps Institute for Tuberculosis Research in Philadelphia, with a large endowment. In 1908 he gave 100,000*l*. to the Johns Hopkins University for the founding of a psychiatric clinic. From the same source we learn that the eleventh industrial fellowship at the University of Kansas has been established by the Pacific Coast Borax Company, of Oakland, California, and will be known as the Borax fellowship. The amount which this company will pay to support the work of its fellow is 150*l*.

WE learn from the *Pioneer Mail* that the Government of Bombay, in a letter to the University Senate, says the offers of contributions which have been made by the leading citizens render it possible to begin the establishment of a central institute in Bombay for the teaching of science. Such an institute is needed urgently in order that the Presidency may have advantages essential to progress which are now reaped by other countries. Before practical steps can be taken in this direction it is necessary to consider what classes of students should be provided for and how the teaching of science can be blended with the system of higher education under the direction of the University. The Governor in Council, after considering the existing curriculum, concludes that radical changes are necessary if the teaching of science and higher education generally are to be brought into harmony with modern requirements.

THE current issue (No. 29) of the *Transvaal Agricultural Journal* contains an article on the desirability of founding a national college of agriculture for the Transvaal. A million pounds is asked for as an endowment, and it is suggested that the college should be thrown open to all students from the British Empire. Mr. F. B. Smith, the Director of Agriculture, has repeatedly urged the necessity for a well-organised scheme of agricultural education in South Africa, and has, indeed, already opened a college at Potchefstroom, under Mr. Holm's principalship. A number of letters from distinguished Americans are printed setting forth the great advantages that have accrued in the United States from the elaborate system of agricultural colleges and experiment stations established there. As the Transvaal already possesses one of the best agricultural departments in the British Empire, it seems fitting that it should also possess the greatest agricultural college.

MUCH educational information of interest and importance is to be found in the latest report of the U.S. Commissioner of Education. We notice that attention is directed to the 1908 report of the Prussian Minister of Public Instruction, which gives a list of twenty-six States comprising the German Empire and their relative university attendances. The list makes it clear that south Germany supplies a relatively greater number of students than Prussia and Saxony. This is noteworthy, because the south has many more small shop industries and smaller farms than the north. The proportion of Prussia would be smaller still if Berlin were excluded. Of the thirteen Prussian provinces, nine remain below the Prussian average. Those districts of the north which are chiefly agricultural furnish few university students, while the agricultural districts of the south furnish many more than the Prussian average, and more than the average of the Empire. Among every 10,000 male inhabitants in east and north Germany in 1905–6, 10·90 were attending universities, in middle and west Germany 12·63, and in south Germany 14·25. Whether analogous results would be noticed if the attendance at technological institutes, agricultural colleges, mining schools, and so on were considered cannot be stated with certainty. In a few years the relative attendance will be greatly changed, since Prussia has opened its universities to women.

THE inaugural address of Prof. H. J. Waters on the occasion of his formal installation as president of the Kansas State Agricultural College, Manhattan, is given in a recent number of *Science* (December 3, 1909). Prof. Waters dealt with the development of the agricultural college in America, and pointed out that, as only one out of every four hundred school children ultimately graduates at college, steps must be taken to bring the work of the colleges to the people. The farmers' institutes do splendid work in this direction, bringing no fewer than one-third of the farmers into personal touch with the college representatives, while as soon as funds are forthcoming the experimental work is to be carried into every county in the State. In justification of these proposals he says, in reference to the past methods of management:—"Ours has been a waste of the resources of soil and forest and stream that is without parallel in the history of the world. This waste has been largely due to improper systems of farming, and cannot continue another century without bringing ruin to American basic industry." The new department of public highways at the college will urge the importance of good country roads, and supervise their construction as soon as the money is forthcoming. In plant and animal improvement, also, the college must lead the way, since it alone can carry on a well-planned programme for an indefinite time. The distinct position occupied by the experiment station was well brought out. Its function was to create agricultural knowledge, not simply to benefit the farmer directly, but to make an exact science of agriculture and enable it to be taught successfully in the colleges, schools, farmers' institutes, and on demonstration farms. Lastly, the rural school problem was dealt with, and this seems to be as far from a satisfactory solution in America as it is here. Not only is there a lack of suitably trained teachers, but, so far, no satisfactory scheme of working the school has been devised. The address is highly suggestive.

THE Education Department of the London County Council has circulated particulars of the science and technology scholarships and exhibitions which are open for competition. The Council is prepared to award in 1910 not more than fifteen scholarships in science and technology, consisting of free education at recognised polytechnics, technical institutes, or institutions of university rank, together with, in cases where the Council thinks fit, maintenance grant, to be fixed after consideration of the circumstances of each candidate, but not to exceed 50*l.* a year in any case, and to be tenable for a period of two years, with a possible extension for a third year. The scholarships will be open to persons engaged in industrial pursuits who have attended evening classes at polytechnics, technical institutes, or colleges of university rank. Also not more than 180 evening exhibitions in science and technology, to be open to persons engaged in or intending to engage in industry, each exhibition to consist of payment of tuition fees, together with a grant of 3*l.* a year, and to be tenable for two years, with a possible extension for a third year. Full particulars of the conditions under which the awards will be made are contained in a pamphlet to be obtained from the L.C.C. education officer. There will be two distinct compeitions, viz. Classes A and B. Candidates for the scholarships must compete under Class B; those for the exhibitions may compete under either Class A or Class B. The teachers' reports will also be taken into account. The award of exhibitions by the competition in Class A will be confined to candidates who, in the case of boys, are less than eighteen, and, in the case of girls, are less than nineteen, years of age on July 31, 1910, and have attended classes in the subjects which they offer for examination for not less than 150 registered hours during the two previous school years at one of the Council's evening schools or evening centres. These candidates will be required to take an examination to be conducted by the Council in certain subjects of general education. Candidates in Class B may compete in either of two ways, by entering for an examination in two subjects, or by submitting works and also undergoing a test examination in one subject. The principals and headmasters or headmistresses of the institutions or schools at which the candidates are in attendance will be asked to submit full reports on their work. In making the award, account will be taken of these reports as well as of the candidates' work in the examination. Fuller particulars of the Council's scholarships, &c., appear in the Council's Scholarships Handbook, published by Messrs. P. S. King and Son, 2 and 4 Great Smith Street, Westminster, S.W., price 1*d.*

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, December 15, 1909.—Prof. W. J. Sollas, F.R.S., president, in the chair.—R. H. **Rastall**: The Skiddaw granite and its metamorphism. The visible exposures of the Skiddaw granite are three in number, all very similar; part of the more northerly one is a greisen, which is not here dealt with. The normal granite is more or less porphyritic in structure, with large phenocrysts of perthite, in a coarse- or fine-textured ground-mass of orthoclase, plagioclase, biotite, and muscovite. Evidence is brought forward to indicate that the granite is intruded along the axis of an anticline, with a strike approximately E. 15° N. and W. 15° S., the normal direction for the district. The metamorphic aureole is very large, measuring about six miles from east to west, and five miles from north to south. This is out of all proportion to the size of the visible exposures of granite, and it is inferred that the intrusion underlies a large area at a small depth. Within this area three distinct rock-types can be recognised, namely:—(1) black slates; (2) grey flags; (3) grey grits. The metamorphism produced in each of these is described in detail, and it is shown that the commonly accepted zones of alteration do not hold, since the rocks concerned were originally of very different character. The phenomena displayed may be summed up as an example of a moderate degree of thermal metamorphism, due to the intrusion of a large mass of granite, at a comparatively low temperature, into a series of rocks of variable composition, which had previously undergone dynamic metamorphism.—A. M. **Finlayson**: The metallogeny of the British Isles. The ore-deposits of the British Isles (tin, copper, lead, zinc, gold) are considered synthetically in their relation to igneous rocks and to tectonics. The great bulk of the deposits of economic importance, including the veins of Cornwall and Devon, the lead, zinc, and copper veins in England, southern Scotland, Wales, and Ireland, are of Hercynian (and Armorican) age. This is shown by the age of the fissuring in many cases (post-Carboniferous to pre-Triassic), by the absence of ore-veins in Jurassic or later formations, and by other evidence. The Tertiary volcanic period was not accompanied by ore-deposition. The ore-deposits are classified according to metallogenetic epochs, and are divided into metallogenetic provinces, as has been done by Prof. L. de Launay with the ore-deposits of Italy, Africa, and Siberia. The essential features of the different groups are summed up. The evidence, collected and sifted, indicates the following zones of ore-deposition:—(1) Pneumatolytic zone: tin, passing up into copper. (2) Deeper vein-zone: copper with gold. Lead and zinc subordinate. (3) Middle and upper vein-zones: lead and zinc. Copper subordinate. The conclusions drawn from the investigation are:—(i) The importance of the physical conditions of the Permo-Trias in favouring ore-deposition in upper zones. (ii) The close connection between metallogenetic and petrographical provinces, and the essential dependence of ore-formation throughout geological time on the differentiation of igneous rocks accompanying great crustal movements. Differences in ore-deposits in different localities and regions appear to be due to primary differentiation of ores accompanying the differentiation of igneous magmas at successive epochs.—F. P. **Mennell**: The geological structure of southern Rhodesia. The author describes in some detail a portion of what may be termed "the Laurentian area" of Africa. The oldest rocks include all lithological varieties, and exhibit most of the known types of alteration. They comprise a great development of hornblendic rocks (epidiorites and amphibolites); on the other hand, mica-schists, and sheared rocks generally, are conspicuously absent. They include (1) "basement schists" on which the altered sediments were laid down, and (2) altered basic igneous intrusions, simulating rocks of any previous age. All these are older than the granites by which they, and the metamorphic series, are invaded. The vertically bedded "ironstone series" is described, and is compared with similar rocks of the Lake Superior region. They are shown to be especially developed along the eastern border of Matabeleland. The conglomerate beds (or Rhodesian "banket") are 10,000 feet thick, and rest unconformably upon the ironstone series in the west, both these formations being gold-bearing. The thick crystalline limestones overlying the conglomerate series contain chert and dolomite, the latter rock occurring also as an alteration product from serpentine. Graphite also is found, and is attributed to the insolubility of carbonaceous matter in a highly siliceous magma. The granites occupy the greater part of the area dealt with, and their intrusive character as regards the metamorphic rocks is shown. No fossils are recorded, other than silicified wood, except in the coal-bearing beds, in which occurs *Palaeomutela keyserlingi* of the Russian Permian, as also plants. The paper concludes with a description of the diamond-bearing beds of Rhodesia, which resemble those of Kimberley, and also contain fragments of eclogite.

Royal Microscopical Society, December 15, 1909.—Mr. E. J. Spitta, vice-president, in the chair.—A. A. C. E. **Merlin**: The measurement of Grayson's 10 band plate.—Dr. M. **Ewell**: A convenient form of stand for use as a micro-colorimeter and with micro-spectroscope.—Dr. J. F. **Gemmell**: An automatic aërating apparatus for aquaria.—F. **Enock**: The life-history of the Hessian fly, with notes on the Tenby wheat midge. Although known in America so far back as 1776, and believed to have been introduced there in the straw mattresses of some Hessian troops, it was not until 1886 that public attention was directed to the Hessian fly in this country. The fallacies then circulated were described and corrected, and the true life-history, as traced by the author, was given. Some notes on observations on the Tenby wheat midge, *Clinodiplosis equestris*, followed.

PARIS.

Academy of Sciences, January 5.—M. Emile Picard in the chair.—Address by the president.—A. **Lacroix**: The existence on the Ivory Coast of a petrographic series comparable with that of charnockite. All these rocks constitute a continuous and comprehensive series passing from granite to a hypersthene almost solely formed of quartz and felspars. The series is interesting as being very rare, and forms a parallel with that of the alkaline and alkalino-calcic rocks.—G. **Koenigs**: Conjugate curves in the most general relative displacement of two bodies.—A. **Demoulin**: The transformation of Ribaucour.—G. **Tsitzéica**: A problem on triple orthogonal systems.—Arnaud **Denjoy**: Uniform analytical functions with discontinuous non-isolated singularities.—Camille **Hautier**: The adiabatic compression of air applied to a vehicle moved by an explosion motor in order to replace mechanical transmission.—A. **de Gramont**: The re-partition of the ultimate rays in the spectrum of different regions in the sun.—E. **Voisenet**: The production of small quantities of formaldehyde in the oxidation of ethyl alcohol by chemical, physical, or biological means. Formaldehyde is constantly formed in the oxidation of ethyl alcohol, free from all trace of methyl alcohol.—E. **de Stoecklin**: A new method allowing of the liberation of traces of alcohols.—L. **Margaillan**: The separation of saccharose and lactose by the "bulgare" ferment.—Pierre **Berthault**: The wild types among cultivated potatoes.—Th. **Mamelle**: The use of potassium cyanide as a subterranean insecticide. This salt injected in aqueous solution in the soil is decomposed by the acidity of the latter, the hydrocyanic acid gas thus permeating the whole.—Mdlle. P. **Cernovodeanu** and Victor **Henri**: A study of the action of ultra-violet rays upon microbes.—C. **Levaditi** and R. **Landsteiner**: Experimental infantile paralysis.—Jean **Boussac**: The nummulites of the zone of the flysch at the west and south-west of the Mercantour.—Héribaud **Joseph**: Investigations on the diatoms of the travertines deposited by the mineral waters of Sainte Marguerite (Puy de Dôme).—E. **Péroux**: The boring of the artesian well of the Maisons-Laffitte.

NEW SOUTH WALES.

Linnean Society, November 24, 1909.—Mr. C. Hedley, president, in the chair.—Dr. H. I. **Jensen**: The variable character of the vegetation on basalt soils. The different types of basaltic country in eastern Australia, and the factors which control the vegetation thereof, may be briefly summarised as:—(1) The tropical or subtropical, coastal basalt scrubs (jungle), with a high rainfall; the soil is very rich, and has a high water-retaining power but low porosity. (2) The extra-tropical, coastal basaltic ranges of southern New South Wales, with a colder climate and a lower rainfall; rapid corrosion and erosion, unhindered by dense vegetation, have given rise to steep slopes, and these have an excellent natural drainage and a stony soil. (3) The almost treeless basaltic plains west of the Great Dividing Range, the dearth of vegetation being due to a low and uncertain rainfall, and sometimes to a cold climate as well. (4) The isolated basaltic knolls of the western interior, usually stony and bare of soil, their barrenness being due to two causes; the basalt is such a compact, homogeneous, and even-grained rock, and the climate so arid, that decomposition is extremely slow, and as the minerals all decompose with about equal readiness, the soil formed is very finely divided, and is removed by the wind practically as fast as it is formed. (5) The basaltic bogs of plains and tablelands, with a water-logged soil due to inefficient drainage, and a soil-water charged with deleterious salts. Hence it will be seen that the defect of basaltic soils is never want of plant-food. The most serious drawbacks are high water-capacity, which causes the asphyxiation of plants in wet weather, and low capillarity power, which impedes a renewal of soil-moisture in droughty seasons.—Dr. W. G. **Woolnough**: The geology of the Tallong-Marulan area, N.S.W. This area has already formed the subject of a communication to the society by Mr. T. G. Taylor and the author. In that paper the physiography was dealt with, and a fine case of river-capture on a large scale described. The district is very remarkable for the great variety of its geological formations. Ordovician, Silurian, Permo-Carboniferous, and Tertiary fossiliferous strata are developed, while eruptive rocks are represented by a great boss of grano-diorite, grading into granite-porphyry and dacite, intersected by complementary dykes of aplitic and lamprophyric character, and by extensive basalts and basalt tuffs. The Ordovician rocks are the nearest to Sydney at present known, and contain abundant beautifully preserved graptolites, series of which have been exhibited at the meetings of the society. The Silurian rocks include two thick belts of fossiliferous limestone in which extensive caves occur. The Permo-Carboniferous rocks are somewhat abnormal in character, lying as they do at the extreme south-western corner of the basin. The formation consists chiefly of coarse conglomerates and breccias. A seam of inferior coal is developed. The grano-diorite mass presents some very interesting problems in magmatic intrusion. It is suggested that it is a laccolitic mass only just laid bare by denudation. The very important problems of magmatic differentiation presented by this mass are not dealt with in this paper. Extensive contact-metamorphism is met with in the district, and a preliminary description of this is given.—E. J. **Goddard**: Contribution to our knowledge of Australian Hirudinea, part iv., with a note on a parasitic endoproctous polyzoon. The paper comprises a detailed account of a leech found in the Brisbane River, which is regarded as indistinguishable from the Jamaican *Pontobdella macrothela*, Schmarda, and descriptions of a species of Pontobdella from the Hawkesbury Estuary, and one of Geobdella from British New Guinea. Certain incomplete but abundant structures adherent to examples of the second of these are pronounced to be the stalks of an endoproctous polyzoon, possibly allied to Loxosoma. Similar structures were erroneously supposed to be the spermatophores of a leech by Macdonald.—L. A. **Cotton**: The tin deposits of New England, N.S.W., part i., the Elsmore-Tingha district. There are three geological units within the tinfield:—(1) a series of slates and claystones; (2) a series of granites; (3) a series of basalts; while a fourth flanks its eastern side. The slates are Palæozoic, and are probably of Silurian age. The basalts are the youngest of the formations, and their age has been determined as Tertiary. The granites are intrusive into the Palæozoic slates, and their age has been provisionally stated as Permian. There are two chief granite types:—(1) the "acid granite" of Mr. E. C. Andrews, which is chiefly a quartz-felspar rock; (2) an older and more basic rock, the Tingha granite. The tin-ore deposits have been found always closely associated with the "acid granite," though post-dating the solidification of that rock. On examining the fracture-systems of Elsmore, Emmaville, and Tingha, it was concluded that the force causing these was a thrust from the east, or a torsional stress having the axis of torsion approximately east and west. It was noted that the system of fractures corresponds closely with the general trend of the tin-bearing belt, both being best developed in a direction about N.E. by E. The tin-ore deposits are discussed under several heads, the chief among them being (*a*) the quartz-quartzose type; (*b*) the quartz-felspar type; (*c*) the pipes; (*d*) the chlorite deposits.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 13.

ROYAL SOCIETY, at 4.30.—On the Atomic Weight of Strontium: Sir Edward Thorpe, C.B., F.R.S., and A. G. Francis.—On the Approximate Arithmetical Solution by Finite Differences of Physical Problems involving Differential Equations, with an Application to the Stresses in a Masonry Dam: L. F. Richardson.—On a Method of Determining the Viscosity of Gases, especially those Available only in Small Quantities: A. O. Rankine.—Recombination of Ions at Different Temperatures: Dr. P. Phillips.—On the Electricity of Rain and Snow: Dr. G. C. Simpson.—On the Polarisation of X-Rays compared with their Power of Exciting High Velocity Kathode Rays: L. Vegard.

MATHEMATICAL SOCIETY, at 5.30.—The Transformations of Coordinates which can be used to transform One Physical Problem into Another:

H. Bateman.—On Homogeneous Oscillation: Dr. W. H. Young.—On the Determination of a Semi-continuous Function from a Countable Set of Values: Dr. W. H. and Mrs. Young.—Note on a Former Paper on th[illegible]ry of Divergent Series: G. H. Hardy.—On the Expression of [illegible]n Function by Means of a Series of Polynomials: Dr. H. F. [illegible]r.—On the Theory of the Cubic Surface: Dr. H. F. Baker.—The [illegible] Functions associated with the Parabolic Cylinder: G. N. [illegible]tson.—Note on the Theory of Sets in Probabilities: Dr. H. de S. Pittard.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Lord Kelvin's Work in Telegraphy and Navigation (*Second Kelvin Lecture*): Prof. J. A. Ewing, C.B., F.R.S.

FRIDAY, JANUARY 14.

MALACOLOGICAL SOCIETY, at 8.—Note on *Helix desertorum*: Mrs. G. B. Longstaff.—Description of *Thersites* (*Glyptorhagada*) *Hillieri*, n.sp., from Central South Australia: E. A. Smith.—Note on *Athoracophorus Schauinslandi*: Henry Suter.—The Ampullaridæ of the Eastern Hemisphere. Description of New Species of Donovania, Scutellina, Fissurella, and Pisania: G. B. Sowerby.—Marine Mollusca from the Kermadec Islands. Notes on Polyplacophora, chiefly Australasian: T. E. Iredale.—Helicoids from New Guinea and Description of a New Species of Papuina: G. K. Gude.

ROYAL ASTRONOMICAL SOCIETY, at 5.—The Moon in Ultra-violet Light: Spectro-selenography: R. W. Wood.—Radial Movement in Sun-spots: *Second paper*: J. Evershed.—On Mr. Fotheringham's Criticisms, *Monthly Notices*, Vol. lxix., pp. 669–73: E. Nevill.—A Last Word on the Correlation of Variable Stars: Karl Pearson.—The Principal Formulæ of Interpolation and Mechanical Differentiation and Integration: H. C. Plummer.—Note on some Sun-spots visible in September, 1909: Col. E. E. Markwick.—*Probable Papers*: Observations of Occultations of Stars by the Moon made at the Royal Observatory, Greenwich, in the year 1909: Astronomer Royal.—Observations of Minor Planets from Photographs taken with the 30-inch Reflector of the Thompson Equatorial at the Royal Observatory, Greenwich, during the year 1909: Astronomer Royal.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Some Uses of Mechanical Power in Engineering Construction: H. F. Donaldson, C.B.

MONDAY, JANUARY 17.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Direct Separation of Emulsions by Filtration and Ultra-Filtration: E. Hatschek.—Significance of the Abel Heat Test of Gun Cotton and Nitro-glycerine: R. Robertson and B. J. Smart.—Note on the Estimation of Iron in Ferric Solution: A. F. Joseph.

ROYAL SOCIETY OF ARTS, at 8.—Textile Ornamentation: Alan S. Cole, C.B.

TUESDAY, JANUARY 18.

ROYAL INSTITUTION, at 3.—The Cultivation of the Sea: Prof. W. A. Herdman, F.R.S.

INSTITUTE OF METALS, at 10.30 a.m.—Address by the President, Sir Gerald Muntz, Bart.

ZOOLOGICAL SOCIETY, at 8.30.—Report on Pathological Observations at the Society's Gardens during 1909: Dr. H. G. Plimmer.—Zoological Collections from Northern Rhodesia and Adjacent Territories: *Lepidoptera Rhopalocera*: S. A. Neave.—On the Marine Fishes and Invertebrates of St. Helena: J. T. Cunningham.—Notes on the Hydroids and Nudibranchs of Bermuda: W. M. Smallwood.—On New or Rare Crustacea of the Order Cumacea from the Collection of the Copenhagen Museum. Part II., The Families Nannastacidæ and Diastylidæ: Dr. W. T. Calman.

ROYAL STATISTICAL SOCIETY, at 5.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further Discussion*: The Design of Rolling Stock for Smooth-rail Working on Heavy Gradients: F. W. Bach.—*Probable Paper*: The Reconstruction of the Tyne North Pier: I. C. Barling.

FARADAY SOCIETY, at 8.—The Conditions which Determine the Composition of Electro-deposited Alloys. Part II., Silver-copper: S. Field.—Studies in the Electro-deposition of Metals: Dr. F. Mollwo Perkin and W. E. Hughes.—The Compressibilities of Helium and Neon: F. P. Burt.—Gas-washing Bottles with very Slight Resistance to the Passage of a Gas: Dr. A. C. Cumming.

WEDNESDAY, JANUARY 19.

INSTITUTE OF METALS, at 10.30 a.m.—*Probable Papers*: The Use of Carbonaceous Filters in the Smelting of Zinc, as employed in the Hopkins Fumeless Zinc Process: C. O. Bannister.—The Properties and Constitution of Copper Arsenic Alloys: G. D. Bengough.—The Failure in Practice of Non-ferrous Metals and Alloys, with Particular Reference to Brass Loco-tubes: T. Vaughan Hughes.—A Contribution to the Study of Phosphor Bronze: O. F. Hudson and E. F. Law.—Notes on a Suggested Record of Analyses: C. A. Klein.—The Analysis of Aluminium and its Alloys: Dr. R. Seligman and F. J. Willott.—The Assay of Industrial Gold Alloys: E. A. Smith.

ROYAL SOCIETY OF ARTS, at 8.—The Japan-British Exhibition, 1910: Count Hirokichi Mutsu.

ROYAL MICROSCOPICAL SOCIETY, at 8.—President's Address: Sir E. Ray Lankester, K.C.B., F.R.S.

ENTOMOLOGICAL SOCIETY, at 8.—Annual Meeting.

ROYAL METEOROLOGICAL SOCIETY, at 7.30, Ordinary Meeting.—At 7.45, Annual General Meeting.—Presentation of the Symons' Gold Medal to Dr. W. N. Shaw, F.R.S.—Presidential Address: Some Relations of Meteorology with Agriculture: H. Mellish.

THURSDAY, JANUARY 20.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Further Observations on the Pathology of Gastric Ulcer (Progress Report): Dr. C. Bolton.—(1) The Velocity of Reaction in the "Absorption" of Specific Agglutinins by Bacteria, and in the "Adsorption" of Agglutinins, Trypsins, and Sulphuric Acid by Animal Charcoal; (2) On the Absorption of Agglutinin by Bacteria, and the Application of Physico-chemical Laws thereto: Georges Dreyer and J. Sholto Douglas.—Observations on the Rate of Action of Drugs (Alcohol, Chloroform, Quinine, Aconitine) upon Muscle as a Function of Temperature: Dr. V. H. Veley, F.R.S., and Dr. A. D. Waller, F.R.S.—An Examination of the Physical and Physiological Properties of Tetrachlorethane and Trichlorethylene: Dr. V. H. Veley, F.R.S.—The Action of Antimony Compounds in Trypanosomiasis in Rats: J. D. Thomson and Prof. A. R. Cushny, F.R.S.—"Amakebe,' a Disease of Calves in Uganda: Colonel Sir David Bruce, C.B., F.R.S., Captains A. E. Hamerton, H. R. Bateman, and F. P. Mackie.

ROYAL INSTITUTION, at 3.—Assyriology: Rev. C. H. W. Johns.

LINNEAN SOCIETY, at 8.—Discussion on the Origin of Vertebrates: Dr. Gaskell, Dr. Gadow, Mr. Goodrich, Prof. Starling, Prof. MacBride, Dr. Smith Woodward, Prof. Dendy.

INSTITUTION OF MINING AND METALLURGY, at 8.

FRIDAY, JANUARY 21.

ROYAL INSTITUTION, at 9.—Light Reactions at Low Temperatures: Sir James Dewar, F.R.S.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Ninth Report to the Alloys Research Committee: On the Properties of some Alloys of Copper, Aluminium, and Manganese (with an Appendix on the Corrosion of Alloys of Copper and Aluminium when exposed to the Sea): Dr. W. Rosenhain and F. C. A. H. Lantsberry.

PHYSICAL SOCIETY, at 5.—Saturation Specific Heats, &c., with van der Waals' and Clausius' Characteristics: R. E. Baynes.—The Polarisation of Dielectrics in a Steady Field of Force: Prof. W. M. Thornton.—On the Use of Mutual Inductometers: Albert Campbell.

LORD KELVIN'S EARLY LIFE.

Lord Kelvin's Early Home. Being the Recollections of his Sister, the late Mrs. Elizabeth King; together with some Family Letters and a Supplementary Chapter by the Editor, Elizabeth Thomson King. Pp. xii+245. (London: Macmillan and Co., Ltd., 1909.) Price 8*s.* 6*d.* net.

THIS fascinating volume gives us a vivid picture of the home life of the remarkable family into which Lord Kelvin was born eighty-five years ago. It is mainly the work of his eldest sister, Mrs. Elizabeth King, who kept many notes and casual diary records, and it has been lovingly edited by her daughter, who has added a brief supplementary chapter. Of that family Lord Kelvin was the last survivor.

Its head was James Thomson, born in 1786, the son of a farmer in county Down, who died in 1849 when professor of mathematics in Glasgow University. His "forbears" had come more than a century before from Ayrshire in the "killing time" of Claverhouse, and the farm on which they settled remained in their possession until 1847, when James Thomson's eldest brother was obliged to leave it for Belfast in the distressful days of the Irish famine.

James Thomson was the Benjamin of the country farmhouse. There were four older children, the youngest ten years older than him. His sister taught him to read, "using handkerchiefs with mottoes and verses printed on them composed by the patriots who brought about the rebellion of 1798." He taught himself arithmetic from a dilapidated copy of Bonycastle, with which he fortunately fell in, "not only mastering its contents, but supplying many pages that were wanting." While still very young he was sent to a day school, and he had no other teaching until he went to Glasgow College. Everything about the boy helped him to educate himself. There was an old sundial in front of the house which fascinated him, and which he tried to reproduce. But his new dials failed to tell the time of day. One very hot summer night, as he lay awake thinking on the problem in his bed out in a garden-house, the theory of dialling dawned on his mind, and he soon worked it out until he was able to make sundials to be placed horizontally, perpendicularly, or at any angle whatever. Some of the dials he made then still exist.

He came across the narrow seas to Glasgow College, as many Irish boys used to do before the Queen's Colleges were set up about 1846. He spent many winters there, taking his M.A., going through most of the medical classes, and the complete theological course with a view to entering the ministry. But when he left the university he was appointed teacher of arithmetic and geography in the newly established Royal Belfast Academical Institution. In a short time it became a college, having preparatory schools connected with it, and it was the forerunner of Queen's College, Belfast. James Thomson was appointed professor of mathematics in the college, in addition to his work in the school. He had found his vocation.

Some time after, when he was thirty-one years of age, he married Margaret Gardiner, daughter of a prosperous Glasgow merchant. She had come across the year before to visit a cousin, Dr. Cairns, a colleague of Dr. Thomson's in the institution. She became engaged to Dr. Thomson, and was married the year following. Their wedding journey was through the Highlands. The Scotch bride settled in Belfast, and died there after twelve happy years of married life. James Thomson brought the motherless family of six children to Glasgow University when he was appointed professor of mathematics in 1832. The eldest daughter, Elizabeth, whose notes and recollections are the basis of the book, was fourteen when they came to Glasgow; the youngest, Robert, was three. They had been seven in number when their mother died. After her death, and before they went to Glasgow, the youngest girl, named after her mother, faded and died. Mrs. Thomson's younger sister, Agnes, who had herself married in 1826, was left in charge of the family, and brought them over to their new home. The family were Elizabeth, aged fourteen; Anna, aged about twelve; James, aged ten; William, aged eight; John, aged six; and Robert, aged four. This younger sister, Agnes—Mrs. Gall—had been brought up in Glasgow by the elder sister, Mrs. Thomson, and felt for her the warm affection of a daughter.

The sixteen years in Belfast, with the young family growing about his knees, were perhaps the most epoch-making of his life. No family ever owed more to their father and mother. For many years, says the eldest daughter, they had no other teacher, except for French and writing, music and dancing. Dr. Thomson

> 'was in the habit of rising at four to work at his books. Some coffee and cream and a spirit lamp having been put ready for him, he made himself a cup of hot coffee before beginning. In these quiet morning hours he got through an immense amount of work before his professional duties began. His books on arithmetic, mathematics, geography, &c., went through very many editions which constantly needed revising and bringing up to date, so that he was occupied with them more or less to the end of his life. As professor of mathematics, during the winter months he lectured every morning from eight till nine, and from eleven to twelve in the forenoon. In the afternoon he was occupied with his school classes, and these ended he regularly went to the news room and the commercial buildings for a little while. Our mother was always waiting for his return, with the children about her. Very eagerly we listened for his knock, and ran to the door, and helped him to take off his things, and then heard some stories from him of what was going on in the world. After dinner we children came down again, and a bit of bright burning cannel coal was put on the fire, which blazed up and filled the room with dancing light; the globes were placed on the table, and we gathered round; little Willie and sometimes James also on the table beside the globes while our father explained their use and taught us to work out problems in them. William was scarcely four when he began to take some part in these cheerful after-dinner lessons, and from the very first he showed the wonderful mental capacity with

which he was endowed. What lovely memories rise up as I recall that dear fireside of long ago—our father and mother sitting there among us."

All his life Lord Kelvin used to testify that his father had taught him everything he had learned until he went to college in Glasgow. Here is another picture of the family:

"It was the next winter that James (then eight) and William (then six) were first sent to some classes in the Institution for an hour or two in the day, and the delightful after-dinner lessons and readings with our dear father were continued with ever increasing profit and pleasure. As we dined at half-past four and the meal was quickly despatched, we had long evenings with him. He gathered us about him, and in every way strove to supply the place of our lovely mother. He was indeed both father and mother to us, and watched over us continually. William was a great pet with him, partly perhaps on account of his extreme beauty, partly on account of his wonderful quickness of apprehension, but most of all, I think, on account of his coaxing, fascinating ways, and the caresses he lavished on his 'darling papa.' When his father stooped to greet him the child would fling his arms about his neck, and smother him with kisses and stroke his cheeks endearingly. . . . I do not remember that any of us were ever in the slightest degree jealous of William on account of our father making him a little more a pet than the rest of us. We were proud of him, and indeed we thought the child petted the father even more than the father petted the child; but we saw plainly that the fondling of his little son pleased him. Willie always slept in a small bed in our father's room—that is, after his early nursery days—because he had for some years a tendency to sleep-walking, which for a time caused some anxiety."

Prof. Thomson's first session at Glasgow brought something of a disappointment. In those days there was no arrangement for a pension—when, through age or infirmity, a professor retired. The outgoing professor often made a private arrangement with the new-comer. Lord Kelvin's sister tells us that under such an arrangement his father actually had at first to pay his predecessor more than the chair brought in.

"To mitigate the loss, he announced an afternoon course of lectures for ladies on geography and astronomy, to be given twice a week in his classroom. Such a thing had never been heard of before in the university, and it was extremely popular. The large class-room was crowded in every corner, and it was a novel and interesting spectacle to see bench rising above bench filled with fashionably dressed ladies, every one looking intent, and many taking notes. All the belles of Glasgow were among the students. This class was carried on for two or three years with undiminished popularity—till the pressure of other engagements compelled my father to give it up, the regular mathematical class becoming so large as to give him quite as much work as he could overtake."

New arrangements also were made with his predecessor, and the ladies' classes had to be given up. The children's education continued to occupy the father's time.

"We did not go to school, but our father, as hitherto, took the general supervision of our lessons. William and James began Latin with him on the Hamiltonian system, and made rapid progress. They also attended the junior mathematical class as listeners, without being examined or writing the exercises. In a letter to William, dated May 7, 1886, Mr. Wallace, an old student of our father's, writes:—'It was in a very large class that as a mere child (ten years old then) you startled the whole class, not one of whom could answer a certain question, by calling out, "Do, papa, let me answer." The impression on my mind has never been effaced.'"

Mrs. King writes again:—

"Our first summer in Scotland was spent at Rothesay, and there our father devoted himself indefatigably to our education. Every morning the four elder children—ages fifteen, thirteen, eleven, nine—spent some hours with him in his study, and always after lessons he took us out for a walk, and made the walk a daily pleasure with his varied converse."

Next session—1834—the aunt, Mrs. Gall, had to leave them to join her husband, and Elizabeth, now a girl of sixteen, became mistress of the house. It is most interesting to follow the course of their studies. The two girls read Latin (Cæsar's Commentaries)

"with our father during his breakfast—our own porridge and milk having been despatched earlier. The two boys, James and William, went in the morning to college classes—the girls taught their two younger brothers piano, and writing, arithmetic, geography, also a little French and Latin, and read Goldsmith's History of England. Nor was poetry neglected in this course of study. I got books from the college library to read about painting and about the lives and works of the old masters. After dinner our father gave us a short mathematical lesson, and after that he read aloud to us. During this winter he thus read the whole of Pope's Iliad and Odyssey, several of the plays of Shakespeare, those also of Goldsmith and Sheridan, besides selections from the old poets. William had the strongest sense of humour of any of us, and not only enjoyed it himself, but set all the little party laughing mirthfully whenever a humorous passage occurred. Mrs. Malaprop and Bob Acres, &c., were most inspiring. Whilst our father read, Anna and I sewed—not fancy work, but flannel petticoats and the like—and our brothers lay on their backs on the floor with their arms extended, to give them a rest and help them to grow straight. The reading was followed by a lively tea, after which our father returned to his study, the two youngest children were taken up to bed, and the four elder adjourned to the drawing-room. James and William were attending Dr. Cooper's natural history class, and in the evenings they retailed their lectures to their sisters after tea. William was not ten till the following June. I was James's pupil, and Anna was William's. About 9 o'clock James and William went to bed, and Anna and I went down to the study to our father, who took down a book and read to us—sitting on two stools at his feet. It was often the Spectator or Rambler that he chose for this purpose—sometimes Blair's Sermons, which he considered pure English as well as profitable reading. In about half-an-hour we said good-night. A servant always came for our candle and took it to him that he might know that we were snug in bed."

"I think it was about the end of 1836, when William was twelve, that James and William made electrical machines for themselves, having become much interested in the study of electricity at the natural philosophy class. James's machine was larger and more carefully finished than William's, but William's, though rather rough, served every purpose to his own satisfaction. They made them entirely themselves. The chief thing that I remember is the frequent shocks to which the family in general were subjected, and the collecting of electricity in their large Leyden jars. But their work was really serious, and was continually expanding. They went on to make voltaic piles and galvanic batteries, experimenting with metals and fluids, and on light and heat, and magnetic electricity. Soon William's attention was turned to the polarisation of light, and he pursued experiments in this field of inquiry with extraordinary eagerness and delight. The brothers contrived and themselves made most if not all of the apparatus they used in their experiments."

"Their happy winter workdays were pleasantly varied with summer rambles. Dr. Nichol, the famous professor of astronomy, had taught these classes in natural philosophy during the illness of the professor, and in summer he took James and William a two or three days' ramble over the volcanic region of the Siebengebirge, climbing the Drachenfels on their last morning."

All science was their province. Lord Kelvin always claimed that natural philosophy comprehended all the sciences.

"Before setting out on our travels in 1840," his sister writes that "William had got Fourier's 'Théorie analytique de la Chaleur' from the college library, and when studying the book one day he suddenly sprang from the stool on which he was sitting and excitedly exclaimed, 'Papa, Fourier is right and Kelland is wrong.' Our father was rather incredulous, but on examination he found that in the points in which Kelland had declared Fourier mistaken it was Kelland himself who was mistaken and not Fourier. He made the boy write an article for the Cambridge Mathematical Journal, and sent it to Gregory, the editor. It was shown to Kelland before it was published. At first he was very much annoyed, but after some expressions had been altered he was satisfied to let it appear. I may add that Kelland became very friendly with William, and as long as he lived the friendship continued."

In 1841 William went to Cambridge, and the story of his life there is well known.

"A brilliant university career was before him. He was also distinguishing himself as an oarsman. A nice second-hand 'funny' came in his way, which he did not lose the opportunity of securing. It was 27 ft. long, painted blue, and bordered with a band of gilding. It was decked or covered all over except a hole in the middle, where the rower sat, and it was so light that William could carry it himself if need were. He called it the 'Nautilus.' He became as enthusiastic in boating as he was in everything he set about, and he won many prizes in the races. Like a jockey, he used to regulate his food so as to form good strong muscle without increasing his weight. . . . When he won the Silver Sculls, it was better, he declared, than winning an examination."

The story of his second wranglership and subsequent first Smith's prizemanship has often been told. When the first list came out he writes to his sister that the principal thing he cared about in the result was the disappointment he was afraid papa must feel, "as I am afraid he had rather raised his hopes about it, though I tried to keep him from expecting too much before the examination, as I knew the uncertainty."

Next year came welcome compensation. At the age of twenty-two William was elected professor of natural philosophy in Glasgow, to the chair which he made so famous during the half-century of his occupation. It was delightful, for his father, now his colleague, was becoming frail. He died of cholera in Glasgow two years and a half later. But he had seen in his declining years the splendid outcome of his long life-work. James Thomson's numerous text-books were excellent in their day. They had an enormous circulation, and were of the utmost service in the education of the time. But his greatest work was his teaching of his own family. While his most enduring monument is the splendid fame of Lord Kelvin and his elder brother, James Thomson, he did work not less memorable in shaping and developing the beautiful lives of all the six children, to whom he was father and mother in one. It was in that warm and loving home that Lord Kelvin and his brothers and sisters found the intellectual and moral nourishment that made them what they came to be in their day and generation. W. J.

PROTOPLASM IN HARNESS.

Les Zoocécidies des Plantes d'Europe et du Bassin de la Méditerranée. By Dr. C. Houard. Two vols. (I. 1908, II. 1909). Pp. xvi+1248. (Paris: A. Hermann et Fils.) Price, two vols., 45 francs.

GALLS on plants, in at least the more conspicuous forms, must have been known to man from a very early period in his history, and the presence in them of living animals might have been expected to suggest inquiries as to their source and relation to plants, yet even after Malpighi had published the results of his study of various galls, and had been followed by Reaumur in his admirable "Mémoires," the interest in those curious growths long remained limited to a very few. To botanists they were little more than excrescences on, or defects of, plants, lessening their value as specimens, while zoologists were rarely attracted to the study of the makers, which belonged for the most part to mites, nematode worms, midges, and other groups difficult to study, and little attractive in themselves.

But the latter half of the nineteenth century was marked by an almost sudden outburst of activity, about 1870, led by Drs. F. Thomas, D. von Schlechtendal, F. Löw, G. Mayr, and others, resulting in numerous papers filled with descriptions of previously unknown galls, and gall-makers, and with life-histories disclosing new relations between plants and animals, as well as new cycles of development of the animals. Such discoveries as the surprising dimorphism so general among the Cynipidæ that gall the oaks attracted keen interest, which showed itself in an increase of workers, and in a more and more rapid advance in the study of galls, especially in faunistic researches, and in more accurate determinations of the gall-makers and of the influence on one another of host and parasite.

The diversities in structure among galls (the alterations induced by the gall-producers in some cases amounting only to slight enlargement of the parts involved, while in others they result in bodies of complex nature and definite specific forms), and the systematic relations among the numerous gall-bearing plants, and also among the gall-producers, support the belief that the power to affect the protoplasm so as to lead it to produce structures useful to the gall-makers has been acquired independently by numerous organisms (plants as well as animals), in widely different grades of development. If that is so, it seems reasonable to expect that power to control the activity of protoplasm will, at least to some extent, be acquired by man, and may produce results of great value. Although as yet experiments have thrown little light on the artificial production of galls, there is a very attractive field open for research in this direction.

Since 1870 an extensive literature has appeared dealing with galls, dispersed so widely that much of it was almost beyond reach of even keen students in this field. In 1858 G. von Haimhoffen estimated the known galls of Europe at from 300 to 350. In Kaltenbach's "Planzenfeinde," issued in 1873 and 1874, the galls of Central Europe formed by insects, and by a few mites, were described under the host-plants; and from 1890 to 1895 D. von Schlechtendal issued a catalogue of the galls of animal-origin then known to occur in Germany.

In 1901 appeared two works giving brief descriptions of the galls of Europe and of the Mediterranean area, Kieffer's "Synopsis des Zoocécidies d'Europe," and Darboux and Houard's "Catalogue systématique des Zoocécidies de l'Europe et du Bassin Méditerranéen." These were most welcome, and stimulated research so greatly that a new catalogue had already become necessary when M. Houard supplied the need by his latest work, "Les Zoocécidies des Plantes d'Europe et du Bassin de la Méditerranée." Based upon the "Catalogue," and covering the same area, comparison of the two shows remarkable progress during the few years that elapsed between their dates of issue. Such a comparison is a little hindered by the host-plants being arranged in the earlier list in alphabetical order of the generic and specific names, while in the later they are in families, these following the order in Engler's "Pflanzenfamilien," while within each family the genera and species are grouped after Nyman's "Conspectus Floræ Europeæ." The advantages derived from the re-arrangement of the host plants beside their allies far outweigh those of the alphabetical arrangement.

The comparison between the individual hosts in the two lists shows very careful revision of the descriptions common to both, the omission from the second of some forms included in the first, the definite reference to their makers of numerous galls previously of unknown or doubtful origin, and the addition of many recently discovered galls, some on plants already known to bear galls, others on new hosts. A rough indication of the advance is given in the rise of the marginal numbers attached to the galls from 4169 to 6239; but perhaps a truer value is afforded by the increase of the host-plants in much the same proportion, and of the known gall-makers from 1072 to 1366 species, the increase being especially large among the Curculionidæ (beetles), the Cynipidæ (gall-flies), the Cecidomyidæ (gall-midges), and Eriophyidæ (gall-mites). Numerous additions have been made to the very useful illustrations scattered through the book.

An important addition is a bibliography of the literature on galls, which, though not complete, is the best that has yet been published, and will be found most helpful as a guide, while its value is increased by references to it under each gall; and the countries in which the galls have been found are also indicated very briefly, yet simply. Under each host-plant the galls are arranged on the same method as was employed in the "Catalogue systématique," viz., terminal galls of fruits, flowers, stems, and buds, followed by lateral growths on roots, stems, branches, leaves, &c. In most cases this method makes it possible to ascertain the name of any gall without serious difficulty; but on some of the oaks and a few other plants the forms are so numerous as to lead to further subdivision of the groups by subordinate characters.

The arrangement of the plants in families has allowed a brief but suggestive outline of the leading features of the galls characteristic of each family, and of occasional suggestions for inquiries.

Careful indexes of the host-plants and of the gall-makers add greatly to the usefulness of the book, and the typography is excellent. It is, in a very literal sense, indispensable to all students of galls, while those interested in the problems as to the nature of living matter and its responses to stimuli will find in its pages much matter for further investigations.

ELECTRICITY ON THE FARM.

Électricité agricole. By A. Petit. Pp. 424. (Paris: J. B. Baillière et Fils, 1909.) Price 5 francs.

THIS book is one of the sixty volumes of the "Encyclopédie agricole," published under the editorship of M. Wery, the scope of which is well summed up in the introduction:—

> "Extraire de notre enseignement supérieur la partie immédiatement utilisable par l'exploitant du domaine rurale et faire connaître du même coup à celui-ci les données scientifiques définitivement acquises sur lesquelles la pratique actuelle est basée."

It is in no sense a popular exposition of the principles of electricity, but is rather written for the intelligent farmer who knows something about electricity and also about engineering, and is enterprising enough to investigate the merits of a new suggestion.

The first chapter is devoted to a recapitulation of the general principles and the system of units employed. No attempt is made to dispense with technical expressions; "connaître le vocabulaire d'un art, c'est déjà connaître cet art." The modes of transforming mechanical into electrical energy are then discussed in a very interesting chapter, the sources of energy dealt with being water power, steam, oil, and wind. Of all these wind would be by far the best if electricity had to be generated on the farm itself, but the difficulties are considerable. Attempts have been made in this direction particularly by M. La Cour in Denmark, whose trials are perhaps the most complete yet made, and who has demonstrated the possibility of utilising wind if there is also some subsidiary source of power. But the subject is by no means exhausted, and the utilisation of the energy of the wind still remains one of the most fascinating problems in agricultural engineering. The transmission of the current is next described. In this chapter, as in the preceding one, there are a number of diagrams to illustrate the principle of the apparatus, besides a good deal of information that will be useful when anything goes wrong. These chapters take up half the book.

The author then comes to the very important subject, How can electrical energy be utilised on the farm? The two applications developed in detail are the driving of engines and lighting. Its use for driving the machinery in the farm buildings, the chaff-cutter, the pulper, and so on, is obvious, but the author goes still further and describes a number of applications which as yet have only rarely been made. Some forty pages are devoted to electrical ploughing, the first attempts at which were made so far back as 1879, although as a practicable method nothing was done until 1894, when a start was made both in Italy and in Germany. The methods are almost exactly the same as for steam ploughing; indeed, the idea is taken direct from the steam plough but electricity is substituted for steam as the hauling power. In one system there are two electric motors at opposite ends of the furrows hauling the plough; in the other an anchor is used and there is one motor only. The problem here is really very simple; if steam ploughing is known to be beneficial electric ploughing will be equally so, and the question resolves itself solely into the relative cost of the power. Indeed, this statement holds true of most of the applications recommended by the author. His electrical threshing machine, for instance, is the ordinary machine driven by electrical power, so also are the refrigerating machines, pumps, and sawmills.

The application of electricity as a source of light affords a great deal of scope for the author's ingenuity, since many of the farm operations, such as the milking and feeding of dairy cows, have to be carried out before daylight during part of the year. Suitable lamps are suggested for the various buildings.

There is also a useful chapter on treatment of accidents caused by electricity and precautions to be taken in order to avoid accidents. Lastly we have some well-illustrated descriptions of farms where some of these applications are in actual use. Probably to the English reader this is the most interesting chapter of all. Whether we may expect to see electricity utilised on British farms is another matter. Up to the present electricity has simply been taking the place of steam to work the old implements originally designed for human or horse labour. Probably before it comes into common use in agriculture our implements will have to be re-modelled and adapted to electrical power. In the cases described by the author water power is available or electric current is being transmitted through the district. The farmer can calculate exactly how much his power will cost him and whether it is worth while replacing the oil engine by a motor.

The book forms a useful contribution to agricultural engineering, and will make very suggestive reading for the thoughtful agriculturist.

THE PHENOMENA OF THE EARTH'S SURFACE.

Physiography for Schools. By R. D. Salisbury. Pp. viii+530. (London: John Murray, 1909.) Price 6*s.* net.

THIS book may be looked on as a reduction of the advanced course by the same author. Prof. Salisbury states in his preface that he differs from other writers on physical geography "as to the points upon which emphasis should be laid and the objects to be attained." But it would require careful reading to find out in what matters of principle this text-book differs from others by American authors, and we fancy that schools will adopt one book or the other rather from some attraction between the teacher and the author than from any preference as to mode of treatment. We miss the "cycle of erosion," and its accompaniment, the "peneplain," which have taken quite an affectionate hold upon our minds; but we meet the "mesa" and the "monadnock," and the really awkward adjective "piedmont," this last being used without explanation, and applied to certain plains as well as glaciers.

Valley-forms are agreeably dealt with as expressions of youth, maturity, or old age, and the excellent chapter on the "Work of Running Water" may be taken as typical of the first part of the book. We should not like to spare any of its numerous maps and illustrations, which bring before us all manner of details in the history of a stream; at the same time, we should like to hear more from the author, whose lines are modestly dovetailed in between them. A specially effective feature of part i. is the insertion of some twenty contoured maps in colour, often on a scale of one inch to one mile, selected from the topographic sheets of the United States Geological Survey. With this example before us, must we wait long for a European work, similarly illustrated from our British contoured maps, and also, perhaps, from the 1:200,000 sheets of the Austrian Military Institute?

The later parts of the book, on "Earth Relations," "The Atmosphere," and "The Ocean," do not lend themselves so temptingly to illustration; but numerous diagrams and charts are given, and the instruction in the text is singularly clear. Fig. 351, showing how the length of a degree is related to polar flattening, requires more thought than a child is likely to bring to bear on it. Perhaps a diagram showing how longer distances have to be traversed as we go northward, in order to shift the altitude of the pole star by so many degrees, might have been simpler, in illustration of the description on the following page. Snow crystals are named "snowflakes" in the title of Fig. 176; and Fig. 450 shows the sounding-tube, and not the line, as stated. We fear that the abrupt question to the reader, "Why not use a rope, instead of a wire, in sounding?" may be taken as a suggestion from the gifted author, and may turn the young mind in a wrong direction. But there is little to criticise in this closely-written text-book. We return to the pages on the work of rivers and of ice with special pleasure. The author thinks (p. 168) that plastic flow does not play any real part in glacier motion, and lays stress on the re-freezing of water that has sunk from above into the ice-mass. The recently published work on glacial phenomena in the Bighorn Mountains has been promptly utilised, and one of the fine cirques, though not our own favourite picture, is shown on p. 179. Chapter xix., on the relations of plants and animals to their environment, has been contributed by Dr. Cowles and Mr. C. C. Adams. G. A. J. C.

OUR BOOK SHELF.

An Atlas of Absorption Spectra. By Dr. C. E. K. Mees. Pp. 74. (London: Longmans, Green and Co.; Croydon: Wratten and Wainwright, Ltd., 1909.)

All scientific workers who have had occasion to employ colour-sensitive photographic plates during the last few years will probably have wished at some time to learn some details as to the specially great advances made in their preparation. Also for the efficient use of the plates suitable screens or colour-filters are required to equalise the action of the various colours. Dr. Mees, as director of the firm of Wratten and Wainwright, has had exceptional facilities in dealing with these matters, and in publishing this atlas he is giving others the benefit of his work. The spectra were taken on the spectrum panchromatic series of plates, which, in addition to the usual region of maximum sensitiveness in the violet, show another maximum near λ 6500 in the red, with gradually decreasing action to λ 7500. To obtain as even records as possible, two schemes were adopted:—(1) For the spectra of dyes an equalising screen of special composition, with two cells of mandarin-orange and P-nitrosodimethylaniline, was used with a Nernst lamp; in the case of special dyes the spectra were photographed in two sections for convenience; in front of the slit a wedge-shaped cell was fitted containing the dye solution, with a similar cell filled with pure water the opposite way to compensate for any prismatic effect. By this means the light passed through varying thicknesses of absorbing medium from end to end of the slit, and the resulting spectra show curves bounding the absorption bands which indicate graphically the change in absorption with varying thickness of dye. (2) For the spectra of the colour-filters the wedge cell could not be employed, and in its place a black wedge of specially prepared glass was used. This gave a range of intensity from 1 to 10,000.

The atlas contains reproductions of the spectra of 170 dye-stuffs, most of them obtained from the Hœchst Farbwerke, and of 76 colour-filters prepared by Messrs. Wratten and Wainwright for various purposes, which are clearly stated. All the photographs are scaled in wave-lengths, so that by mere inspection the exact range of any absorption may be ascertained. A concise index is given, including the name of dye, concentration, source, whether it is acid or basic, and a scale of numbers representing the relative stability to light. Series of monochromatic filters are supplied and illustrated, which practically isolate a very small portion of the spectrum in each case, these being suitable for work requiring great precision in the wave-length of light employed.

Physiology of Man and Other Animals. By Dr. Anne Moore. Pp. xiii+212. (New York: Henry Holt and Co., 1909.) Price 80 cents.

This little book is intended for the use of children in schools; about half of it is devoted to elementary physiology, and the remainder to elementary zoology. The author has the gift of putting things clearly, and in a manner likely to interest the young. She, however, very soon gets out of her depth, and often makes mistakes of the most elementary nature. This is particularly noticeable when she speaks about the nervous system or strays into the region of chemical physiology. There is no clear distinction made between the central and the peripheral nervous system, and no mention made of the functions of the brain as the organ of mind; the depressor nerve is stated to cause slowing of the heart, and the sympathetic nerves, we are told, received their name because of their extreme sensitiveness.

Her definition of osmosis would not be acceptable to any physicist or physiologist; she has not even grasped the distinction between internal and external respiration. We are told that carbon dioxide stimulates the respiratory *muscles* to action; that the secretion of the sebaceous glands is a part of the secretion of the sweat glands; that lipase is the most important ferment of the pancreatic juice; that peptones are absorbed and pass to the liver; that fats are hydrocarbons; and that the formula for starch is $C_6N_{12}O_6$. Such examples of glaring errors are quite sufficient to show that the book cannot be recommended as a safe guide to those who have passed childhood, and even for children it seems a pity that some degree of exactness should not be aimed at.

Deutsche Südpolar-Expedition, 1901–1903. Bd. ii. Geographie und Geologie. Heft 5. Pp. 348–410; pls. xxviii–xxx. (Berlin: Georg Reimer, 1909.) Price 8 marks.

The German South Polar Expedition called for a few hours at the islands at St. Paul and New Amsterdam, and though in so short a visit but little fresh information was obtained, one of the valuable by-products of the expedition is a useful summary and discussion of all that is known about these islands. New Amsterdam was discovered in 1522 by Sebastian del Cano, who commanded Magellan's expedition after his death at Manila. Both islands are French possessions. They are both solely volcanic, and rise from a common base. New Amsterdam is composed only of basalt, while St. Paul consists of basalt with some rhyolite tuffs and obsidian. The memoir on the geography of the islands is by Dr. von Drygalski, on the geology by Philippi, and on the petrology and the relations of the lavas to those of Kerguelen, Possession, and Heard Islands by Reinisch. E. Vanhöffen contributes a catalogue of the flora and of the fauna, which consists only of insects, myriapods, spiders, tardigrades, crustacea, rotifers, &c. The memoir has three excellent plates illustrating the scenery and volcanic features.

Les Progrès récents de l'Astronomie (1908). By Prof. Paul Stroobant. Pp. 115. (Brussels: Hayez, 1909.)

Everyone interested in the progress of astronomy will welcome the appearance of Prof. Stroobant's annual summary of a year's results, and 1908 was by no means a barren year. Hale's discovery of the Zeeman effect in the solar spectrum, the Flint Island eclipse, the Lowell Observatory observations of the planets and their spectra, the discovery of J viii by Melotte at Greenwich, and the preliminary comet campaign provided by the appearance of 1908 III, are all reviewed in a fashion at once comprehensive and clear. The omissions are few, but we regret to find no mention of the McClean expedition to Flint Island. Four plates illustrate various researches, and the tables of results will be found useful for reference. Although each result appears under a general and a special heading, the addition of an index to this small volume would, we believe, enhance its value.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Cross-fertilisation of Sweet-peas.

IT is unnecessary, I think, to cite more than one of the recent statements with regard to sweet-peas, though I can provide others. Sir Francis Galton in his just issued "Memories" (p. 300) writes:—

"After much consideration and many inquiries, I determined in 1885, on experimenting with sweet-peas, which were suggested to me both by Sir Joseph Hooker and Mr. Darwin. Their merits are three-fold. They have so little tendency to become cross-fertilised that seedsmen do not hesitate to grow differently coloured plants in neighbouring beds. . . ."

I must thank Mr. Francis Darwin (p. 308) for his reference to the "Cross- and Self-fertilisation." On the page he refers to Charles Darwin writes:—"Why, then, do not the varieties occasionally intercross, though this would not often happen, as insects so rarely act in an efficient manner?" and again, "Whatever the cause may be, we may conclude, that in England the varieties never or very rarely intercross." These are the views which evidently Charles Darwin communicated to Sir Francis Galton.

My point is that *now* they do intercross, and that varieties cannot with safety be kept in neighbouring beds. Mr. Wright, the superintendent of the Royal Horticultural Society's Garden at Wisley, told an inquirer in 1907, as to his experience *re* sweet-peas, that he had no doubt there was some English insect that cross-fertilised them, and that in trying new sorts the gardeners had to place the rows in different parts of the garden to minimise the risk as much as possible. Charles Darwin, in the passage referred to, says that "on two or three occasions" he saw Megachile in the act of depressing the keel, and he notes that these bees had the undersides of their bodies thickly covered with pollen. My point is that hourly every day these bees came in large numbers; their visits were not occasional, but persistent and effectual; I never saw a hive bee, although they frequently tried, successful. Megachile may, in the course of forty years, have developed the habit much more completely. The purport of my letter was merely to suggest to those growing sweet-peas that there is no security that they will be self-fertilised if Megachile be frequent.

I should like to add that "The Original π" is by no means the first π who has contributed to the columns of NATURE! The π's are a large and talkative species.

π.

The Village Institute and its Educational Possibilities.

THE growth of social life in villages during the last few years has been fostered by the erection of village institutes, halls, and reading-rooms, and yearly such institutions are becoming more numerous. Has the educational life of the village been fostered by their growth?

The majority of these institutions cater for games and recreation, together with a supply of reading matter of the daily paper and monthly magazine type. The presence of the latter indicates a desire on behalf of the management or the donor of the institute to devote at least part of the work of the institute to educational purposes. In many institutes the reading-room is little frequented and has the least share of the members' time, whereas the billiard-room, where long visits are the rule, invariably presents a scene of congestion.

To a certain extent the village institute is a replica of the mechanics' institute of the towns and urban districts; both serve as a meeting place for members, and supply opportunities for recreation and self-improvement to them.

The mechanics' institutes were, in their earliest days, the housing place of evening classes in science, art, and languages, but the growth of continuation education has led to the general abandonment of the mechanics' institutes for systematic class instruction and the provision of special buildings. Courses of lectures of a more or less educational character still remain at the mechanics' institutes—remnants of their early educational efforts. The mechanics' institute is a model upon which the village institute might shape its policy and methods, so becoming a centre of educational activity.

As a result, we find that several village institutes, like their town compeers, give courses of lectures. Such subjects as agriculture, horticulture, poultry-keeping, bee-keeping, and other rural industries are so treated, but, generally speaking, the village institutes have never attempted to take up the work of systematic evening education, as the mechanics' institutes did, fitted to the environment of the villager.

The future of an individual is as much a problem for the "powers that be" in a rural community as it is in the urban district, town, or city. This future is not thoroughly and properly catered for by providing the individual with games and recreation to the exclusion of provision for craft-work and intellectual training for his daily work. Why should not the village institute help in the intellectual development of villagers, keeping them mentally elastic and manually efficient by suitable educational work?

If the institute cannot provide suitable educational provision on account of lack of funds, it certainly should not, by its rules of membership or otherwise, be an obstacle in the way of other institutions which take up evening classes.

The younger members of rural communities, as in towns, after leaving day school generally display no further interest in their own education, and their elementary education equipment begins to rust.

In the towns we appeal to the employer to look after the welfare of the youth by asking him to see they attend the evening school. In the villages the same appeal may be made by way of the village institute. The appeal in each case would cease if continuation work became compulsory, but as at present compulsion is not a part of either political party's programme, we must look to other means. It may be said there would be no resting and rusting of the villager if there were an evening continuation school in the village, a statement which brings one to the *raison d'être* of the present letter on village institutes.

The village institute has usually no restrictions concerning the admission of a youth when he applies to become a member. It would not be necessary to advocate a restriction if institute managers had, as a condition of membership, told the would-be member that the institute would be closed to him on those nights the evening school was open. It would not be too drastic to tell the would-be member that up to eighteen years of age he would be expected to attend the evening classes held in the village. In small villages, where the number of available students for an evening school is small, the village institute should render all the help it can. A leading educationist stated before the recent Consultative Committee on Attendance at Evening Schools that there was a club where no boy was allowed to remain a member unless he attended the evening classes two nights per week. The village institutes might take up a similar definite position where evening schools are in existence.

The foregoing suggestions are made because the institute, by providing games, not only threatens the existence or birth of an evening school, but cultivates in its young members no sense of responsibility either to themselves or to the community. A curriculum of pleasure alone should be far from satisfactory for the leaders of village activity.

It may be said that an institute cannot afford financially to cripple itself by the adoption of the foregoing suggestions. My reply is that managers would find that such a regulation, prospective in nature, would not reduce applications for membership. Temporarily there might be a little resistance to the conditions, but in time applicants would become educated to the benefits of such a regulation and recognise it, as they do the payment of a fee. The authority managing the evening school might transfer the fee from the school to the institute if the student made a satisfactory percentage of school attendances. Thus the student would not be mulcted in two payments, one for the school and another for the institute.

It does appear plain that the village institutes have a fine opportunity for giving encouragement to continuation rural education; they not only miss the opportunity, but, at the same time, unwittingly are the cause of there being no demand for an evening school. Opportunities for the village youth to spend aimlessly and uselessly all their spare time are to be deprecated.

In one West Riding village the influence of the opening of a new institute was shown by the total exodus of the members of the existing evening school. Even the moral obligation to complete their attendances, so as to save financial losses upon the school, failed to bring them back again. The billiard-ball was rolling, so opportunities for the making of more fit citizens were sent flying. The result was not a moral triumph for the ex-students.

May one suggest that in the future some donor of an institute, or someone who by their contribution has made it possible for trustees to lease an institute at a nominal rent to a committee of management, should insert a proviso in their deed of gift that younger members of the institute are to attend continuation educational work at the village school? Such a proviso might be open to elimination if found, after an extended trial, to be prejudicial to the institute's success.

There should be an educational side to every village institute; it might be an attached rural association or club for the further advance of rural interests. Such an association might hold meetings periodically for discussions upon general agricultural matters. Samples of manures and feeding stuffs, along with a consideration of current values and prevalent adulterants, are important matters, and should be undertaken by the suggested rural club. The leaflets of the Board of Agriculture would be suitable for elucidation and discussion; their distribution could be carried out by the club.

Village halls have been in the past the centre of the arts and crafts movement; in some parts of the country they are yet. The development of handwork in the elementary schools of the rural districts should again revive the use of the village hall. Such a revival requires funds. The Board of Education and local authorities place at the disposal of committees doing educational work of a manual nature liberal grants. Some of the wealthy trade guilds might be disposed to find funds for a village development of arts and crafts if the work had an industrial basis. In this way might be developed in the village, as in Germany, a large number of small workshops going hand in hand with agriculture.

The village institute and evening school would not become competitors by both taking up educational work; they would become helpers. Admission to the institute's higher work should preferentially be given to those who had thoroughly prepared themselves for it by a satisfactory course of preparatory work at the evening school. In short, the institute would be regarded as the technical school of the village, giving, amongst other work, practical and theoretical instruction on the greatest of all industries—agriculture.

Avogadro's Hypothesis (or Law).

IN Prof. Tilden's "Life of Mendeléeff" in the current number of the Journal of the Chemical Society, I see that he refers repeatedly to the "law" of Avogadro. Sir William Ramsay, in his "Modern Chemistry," speaks of it as a "hypothesis," and this has surely been, until recently, the practice of chemists.

I think there is a growing tendency to speak of it as a law. This, doubtless, arises from the strong confirmatory evidence provided by modern physical chemistry. It is desirable, in the interests of students and of exactitude in scientific nomenclature, that some decision should be come to as to which term should be used. This may necessitate very careful definition.

A discussion of this matter, in which teachers will give reasons for their choice, should prove of value.

Parmiter's School, Approach Road, Victoria
Park, N.E., January 17.

"A Japanese Priest in Tibet."

WHATEVER may be the demerits of Mr. Kawaguchi's "Three Years in Tibet," reviewed in NATURE of January 13, the title of the book is, according to the Eastern habit of reckoning, quite accurate. Mr. Kawaguchi spent part of 1900, all 1901, and part of 1902 in Tibet—three years. A child in Japan, if born on December 31, begins his second year on January 1, and on the succeeding New Year's Day may be regarded as having lived for three years, although he may be only 367 days old!

C. G. KNOTT.

University of Edinburgh, January 17.

STANDARD MEASUREMENT IN WAVE-LENGTHS OF LIGHT.

THE employment of the principle of the interference of two rays of monochromatic light, derived from the same source, one retarded behind the other by having to traverse a longer path, for the production of rectilinear interference bands constituting a scale of half-wave-lengths, has now been brought to such perfection that this highly refined scale may be used for the measurement of short distances or small movements of any description whatsoever. The accuracy is absolute to the tenth part of a scale division, the twentieth part of a wave-length of light, and is actually measurable with the most ordinary micrometer to the one-hundredth of a scale division, corresponding to the two-hundredth part of a wave-length. Now a wave-length of even the grossest radiations employed, those of red light, derived from either cadmium vapour (0·0006438 mm.) or hydrogen (0·0006562 mm.), is a forty-thousandth of an inch, so that the measurable unit is an eight-millionth part of an inch.

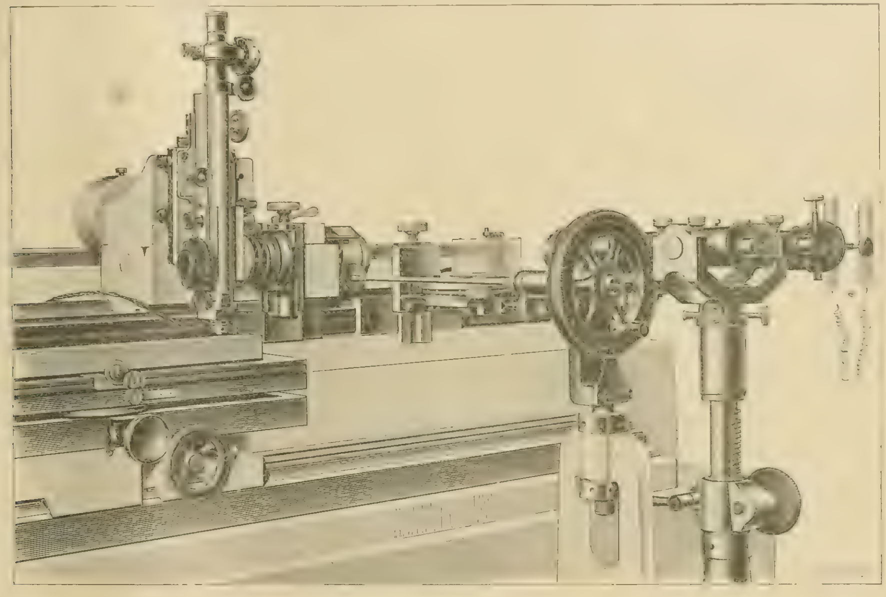
The finest trustworthy measurement by mechanical means (such as the Whitworth machine) or micrometric devices (such as the most refined thickness measurer) is the one-thousandth of a millimetre, or the twenty-five-thousandth of an inch. Moreover, the amount of possible error with either of these mechanical methods of measurement or the interference method is from one to two units of the respective scales. Hence the interference method is only subject to a possible error of one three-hundred-and-twentieth the magnitude of that to which the mechanical mode of measurement is liable.

The interference method was first seriously employed by Fizeau, who utilised it for the determination of the thermal expansion of crystals and other small bodies. It was materially improved by Abbe and Pulfrich, and more recently both for the same crystallographic purpose and for general purposes by the writer, who has also extended its use to the measurement of the modulus of elasticity of crystals and small bodies or small quantities of substances in general.

It will be remembered also that Prof. Michelson, of Chicago, has recently adapted his entirely different mode of producing interference fringes, in this case circular, to the determination of the number of wave-lengths of red cadmium light, which he has proved to be the most homogeneous of all radiations yet known to us, in the French metre. By employing a graduated series of glass-plate *étalons* or intermediate standards, each double of the preceding one, commencing with a basal one of half a millimetre in which the actual number (1212) of half-wave-lengths was counted, the number of wave-lengths of red cadmium light in the metre was eventually found to be 1,553,163. This number has since been confirmed by the independent method of Fabry and Perot, in which circular fringes are also produced.

Three years ago the writer was invited by the Standards Department of the Board of Trade to adapt his interferometer to the purposes of a wave-length comparator of measures of length, and a memoir recently published in the Philosophical Transactions of the Royal Society (Phil. Trans. A, 1910, vol. ccx., p. 1), with the consent of the President of the Board of Trade, describes the instrument, which has now been installed in the Standards Office. The memoir also comprises an appendix concerning the possible employment of wave-length rulings on metal as defining lines on standard bars, with suggestions for their use along with the interference bands of the interferometer, in an original method of determining the total number of wave-lengths in the British yard.

A general view of the interferometer and one of the duplicate microscopes of the comparator, together with sufficient of the bar-carriage to enable some idea of the whole apparatus to be gained, is given in the accompanying illustration.



Central part of comparator, showing interferometer.

The whole instrument is mounted on a large stone block, resting on isolated concrete foundations. On a small stone pedestal, similarly isolated, in front of the large block, rests the pedestal of the autocollimating telescope and attached Geissler tube of the interferometer. In the common focal plane of the telescope objective and eye-piece, opposite the junction of this main optical tube with the rectangularly attached side-tube carrying the Geissler tube, a small totally reflecting prism is arranged, half covering the focal aperture. A still smaller rectangular stop or opening in a plate in front of and almost touching that one of the perpendicular prism faces which is directed towards the objective, and lies in the focal plane very close to the edge, dividing the closed half from the open half, is the effective source of the interfering light; the rays from the Geissler tube, received on the other face of the right-angled prism, are arranged to fill this stop after reflection from the hypotenuse of the prism. The rays proceed from the stop to the objective, which they are arranged to fill with light, and thence pass out of the telescope as parallel rays, in the path of which the dispersion and interference apparatus is placed. The rays return to the telescope from the latter along practically the same path, but after re-entering the telescope, instead of returning to the little rectangular stop, their origin, they are deflected just sufficiently to one side to form an image of the stop, the same size as the original, in the open semicircular aperture of the focal plane, within a couple of millimetres of the real stop. This closeness to identity of path of the outgoing and incoming rays, and consequent normal incidence on the reflecting glass surfaces of the interference apparatus, is largely responsible for the magnificent field of parallel straight-lined interference bands which the author's interferometer affords, for it fulfils an essential condition for perfect interference.

With the ordinary eye-piece in position, the images of the stop reflected from the various surfaces of the interference apparatus can be focussed, adequately magnified, and viewed during their adjustment to the theoretically ideal positions. But when this eye-piece is replaced by a special one consisting of a Ramsden micrometer combined with an additional lens between the latter and the focal plane, the telescope is converted into a low-power microscope, which focusses simultaneously the interference bands, a little silvered reference ring in the centre of one of the two surfaces reflecting the interfering light, and the micrometer spider-lines. There are two parallel vertical spider-lines; one is adjustable by the left drum-head of the micrometer, so as to be able to set it at any convenient distance from the other in order to include a single band and most of the reference ring between them; and both are moved together by the other (right) measuring drum, in order to be able to determine the band-width and any fraction of a band which may have passed the reference centre.

The dispersion apparatus consists of a Hilger constant-deviation prism, which enables the desired spectrum ray to be isolated from all others, and that alone delivered to the interference apparatus. The rays are deviated exactly at right angles by this prism towards the interference apparatus, the surfaces of which they strike at normal incidence, after which they return through the constant-deviation prism (thus securing double dispersion) to the telescope. The prism is mounted on a divided circle, so that it may be calibrated for the delivery of light of any desired wave-length, if desired, and has numerous adjustments. Such calibration is not essential, however, as the particular image of the origin-stop in the colour corresponding to the spectrum bright line of cadmium or hydrogen can be adjusted visually on removal of the front lenses of the Ramsden eye-piece.

The interference apparatus consists of three circular and thick glass discs, the third of which is of black glass polished an absolutely true plane on its outer surface, which is one of the two important surfaces concerned in the production of the interfering light. It is ground on the back surface, by which it is attached in an adjustable manner to the right microscope of the comparator, the movement of which it is to record. The other two are larger discs of colourless glass, identically similar, the two truly plane surfaces of each disc not being strictly parallel, but inclined at the minute angle of 35 minutes. The left surface of that one nearest to the black glass disc is the second surface concerned in the interference, and approaches the black glass within a millimetre; the second is a duplicate one, merely introduced on the right of it to correct for the slight dispersion produced by the 35′ of inclination, the two being set oppositely as regards the direction of the wedge. The 35′ inclination is just adequate to deflect out of the field of the telescope the reflection from the other (right) surface of the left colourless disc, and both images from the countervailing disc are got rid of by a slight tilt in the rectangular direction. All the many adjustments required are provided for in the mounting of the two colourless discs, on a separate carrier sliding along the face of the upper V-and-plane bed of the comparator.

The apparatus as described up to this point is the interferometer.

The comparator consists of two V-and-plane beds, nearly 7 feet long, of specially homogeneous cast-iron, and worked truly plane with consummate care, together with their contents; they are arranged step-wise, one on the top of the stone block, and the other 7½ inches below and in front. On the upper one slide the two duplicate microscopes, and on the lower one the standard-bar carriage and accessory fine-adjustment fittings. The carriage is given a longitudinal motion, a transverse motion adequate to bring either of the two bars to be compared under the microscopes, as well as fine adjustments for azimuth, height, and level, thus enabling the defining marks on the bars to be readily focussed without touching the microscopes if it is so desired.

Each microscope is carried on a solidly constructed slider on the V-and-plane bed, by which its coarse adjustment for position is effected. The microscope-bearing bracket is not, however, fixed directly to this slider, but to a second one sliding over the first, also with V-and-plane contact, and with the further control of the movement of a cylinder within a cylindrical boring. The fine-sliding is effected by means of a most carefully made screw of fifty threads to the inch, on which the success of the instrument depends, and which carries at its outer end a large milled head for hand rotation, and a worm-wheel of 100 teeth gearing with an endless screw, which can either be rotated by hand by means of a milled head or by means of a shaft and a large wheel seen in front in the illustration. One complete rotation of the latter corresponds to the movement of the microscope and the black glass interference disc to an extent which causes the passage of fifteen interference bands past the reference centre. More than an inch of movement of the circumference of the wheel is necessary to effect the passage of a single band. Two-thirds of the dead-weight of the microscope and slider are taken up by four spring pistons, and the movement of the slider by the screw is only a push in either direction against the walls of a recess in the free slider, there being absolutely no strain anywhere. Hence this movement of the microscope is not only an excessively fine one, but also so steady that the bands pass with a precision which leaves nothing to be desired, and each band may be held for any length of time for counting purposes.

Each microscope is provided with a micrometer eye-piece, with spider-lines arranged as in the interferometer. The fine adjustment is made exceptionally steady and regular. Two sets of objectives are provided, one pair for observing the defining lines in the countersunk wells near the ends of standard bars, with a magnification of 150 diameters, and without penetration of the well by the objective, and the other set for use with the wave-length rulings.

The defining lines, of whatever character, are illuminated (with "critical illumination") by the brilliant image of a distant Nernst lamp, with the aid in each case of a little reflecting prism, a collimating lens, an iris diaphragm, and a glass-plate mirror above the objective, all provided with fine adjustments. This avoids all heating effect on the bars, and the last traces of heat rays are filtered out by a thick water-jacket in front of the lamp and its beam-parallelising lenses. The illumination of the wave-length rulings one-forty-thousandth of an inch apart is excellent with the 1/12th inch dry objectives employed, and the definition truly surprising.

The temperature of the whole comparator room is maintained at the official temperature, 62° F., entirely electrically, both as regards artificial heating and the thermostat, which is original. So sensitive is the latter that the entrance of a person into the room is immediately followed by the extinction of one of the heating lamps to compensate for the extra warmth introduced.

The finest defining lines yet employed on any line-measure bars are those on the platinum-iridium copy of the imperial standard yard. Yet even each of these has a thickness equivalent to fifteen interference bands. The defining lines on the imperial yard itself are three times as coarse. Hence we have now arrived at that stage in the competition between defining lines and refinement of measurement when the latter has far surpassed the former. It was for this reason that the writer took up the investigation of wave-length rulings, with the idea of their possible use as defining lines commensurable with the increased refinement of measurement. Mr. H. J. Grayson, of Melbourne, whose wonderfully fine rulings have recently been much discussed in microscopic circles, has kindly made a number of rulings of 1/40,000th inch fineness, which preliminary experiments indicated as feasible for the required purpose, on polished speculum-metal and platinum-iridium, which appear, particularly the former, perfectly satisfactory. The forty-thousandth of an inch being the wave-length of red hydrogen or cadmium light, the distance between two lines ruled at this interval corresponds to only two interference bands. With the 1/12th inch dry objectives the lines, moreover, are as cleanly cut as spider-lines, and the thickness of a line is less than half a wave-length. Five such lines are ruled in succession, the central one being considered as *the* defining line. A strong finder-line is ruled on each side of the five, and two other strong ones at right angles in order to localise a central part of such a system. It appears perfectly feasible to carry out a stepping-off process for the counting of the total number of wave-lengths of cadmium red light in the British yard, in which such rulings would take the place of the glass plates of the Michelson or Fabry and Perot *étalons*, a base line of the thirty-second part of an inch being first actually counted in bands with the aid of the interferometer, between limits defined by two such systems of rulings. The final fraction of every stage in such a process could be absolutely checked by the interferometer in all cases where Michelson found it possible to do so, that is, so far as interference bands are still visible, about four inches; and, as it has already been proved that the accuracy with the rulings is almost as great as with interference bands, this checking ceases to be as imperative as when only the coarse existing defining lines are available. Hence, the future before these rulings appears likely to be both interesting and important.

A. E. H. TUTTON.

SOME NEW NATURE BOOKS.[1]

(1) IN this series of pleasantly written essays Mr. Larken gives an account of some of those features of English (and Scotch) country districts which usually appeal to nature-lovers. The author's habit of passing lightly from one topic to another but distantly connected with it produces a certain disjointedness of style and some needless repetitions, but, taken as a whole, his book is quite good to read, and his knack of interesting one in a disputed point and then abruptly leaving it unsettled is well calculated to stimulate personal observation on the part of his readers.

When attempting to draw conclusions himself, however, he is less happy, being prone to derive the inherited instincts and habits of an animal directly from the experience of its ancestors. Moreover, one has rather frequent cause to doubt the accuracy of his statements; for example, anyone familiar with the Caligidæ, and the tightness with which they can adhere, either in or out of the water, even to the smooth sides of a glass dish, will certainly question the remark on p. 219 that a salmon "leaps . . . into the air for the purpose of getting rid of the sea-lice which are attached to him." That "the Brimstone is a genuine child of spring" in contrast with the hibernating Vanessid butterflies (p. 244) is contrary to the experience of other entomologists; and "Humming-Birds of New Guinea" (p. 192) should presumably read "Sun Birds of New Guinea," for humming-birds are confined to western America and its islands.

The book is illustrated with a profusion of excellent plates, chiefly from photographs. As the greater part of it is concerned with ornithological matters, it is not surprising to find that the majority of the illustrations are of birds' nests. The plate of the comma butterfly, which we reproduce, is one of a short series of admirable insect studies.

(2) These four little volumes will be useful to those who wish to interest children in natural history. They treat of the varied aspects of their several subjects in a clear and interesting manner, and are well illustrated by plates (both coloured and from photographs) and by figures in the text. One hesitates to criticise such admirable books at such a low price, but the value of some of the plates would certainly be increased if they could be brought more closely into connection with the chapters which they illustrate; and where this is impossible reference should be made to them in the text. Some statement of the scale of many of the figures would make these much more useful; in chapter ix. of "The Common I Know," where this is particularly needed, it could easily be made by the insertion beside each figure of a line indicating the length of the living specimen. On p. 30 of the same volume the association of two figures of plants drawn to different scales is apt to mislead. But even as they stand we are far from wishing to condemn the figures. Apart from size, they show clearly the salient characters of the objects described; the reproduction of the photographs has been beautifully executed, and the coloured plates are wonderful at the price. We can thoroughly recommend the books for (elementary) school use.

Comma Butterfly. From "Leisure Hours with Nature."

(3) This "collection of literary extracts to accompany a course of nature-study" includes prose and poetry, with a variety of subjects ranging from Ruskin's "Plants" and Thoreau's "Brute Neighbours" to fairy stories such as "The King of the Vipers" and Ruskin's "Visit from the South-West Wind." Several of the extracts are old favourites

---

[1] (1) "Leisure Hours with Nature." By E. P. Larken. Pp. xv+263. (London: T. Fisher Unwin, 1909.) Price 5*s*.

(2) "The Wood I Know"; "The Meadow I Know"; "The Stream I Know"; The Common I Know." Edited by W. P. Westell and H. E. Turner. Pp 77 each. (London: J. M. Dent and Co., 1909.) Price 8*d*.

which have long figured in school "readers," and the others, though less familiar in this *rôle*, are none the less fitted for it. The book is nicely illustrated, and concludes with a short glossary of the rarer words and phrases found in the extracts. It may be recommended for class purposes.

THE BOSTON MEETING OF THE AMERICAN ASSOCIATION.

THE sixty-first meeting of the American Association for the Advancement of Science and of its affiliated societies was held in Boston, Mass., December 27, 1909, to January 1, 1910, under the presidency of Dr. David Starr Jordan, of Leland-Stanford University, California. The meeting was a large one, nearly 1100 members of the association being registered, and the total number of men and women of science in attendance was not far from 2000. The number of affiliated societies was larger than usual, numbering thirty in all. The meetings were held in the buildings of the Massachusetts Institute of Technology, in certain of the buildings of Harvard University, Cambridge, and the new Harvard Medical School in Boston. These three groups of buildings are rather widely separated, and for this reason it was difficult to bring together the exact registration.

The opening session was held in Huntington Hall, Massachusetts Institute of Technology, on Monday morning, December 27. Addresses of welcome were given by President McLaurin, of the Institute of Technology, and by Dean W. C. Sabine, of the Graduate Scientific School of Harvard, representing the president of Harvard University. On Monday night the address of the retiring president, Prof. T. C. Chamberlin, of the University of Chicago, was delivered in Sanders Theatre, Harvard University. His subject was a geologic forecast of the future opportunities of our race. The address was preceded by an address of welcome at Harvard University by Prof. F. W. Putnam, a past-president of the association, and who, from 1873 to 1898, was its permanent secretary. After the address a reception was held by the corporation of Harvard University in Memorial Hall. During the week the addresses of the vice-presidents (or chairmen) of the sections were given on the different afternoons as follows:—

Vice-President Keyser, before the Section of Mathematics and Astronomy, the thesis of modern logistic; Vice-President Guthe, before the Section of Physics, some reforms needed in the teaching of physics; Vice-President Kahlenberg, before the Section of Chemistry, the past and future of the study of solutions; Vice-President Swain, before the Section of Mechanical Science and Engineering, the profession of engineering and its relation to the American Association for the Advancement of Science; Vice-President Willis, before the Section of Geology and Geography, the principles of paleogeography; Vice-President Herrick, before the Section of Zoology, evolution of intelligence and its organs; Vice-President Richards, before the Section of Botany, the nature of response to chemical stimulation; Vice-President Woodworth, before the Section of Anthropology and Psychology, racial differences in mental traits; Vice-President Holt, before the Section of Social and Economic Science, the gold question; Vice-President Howell, before the Section of Physiology and Experimental Medicine, chemical regulation in the animal body by means of activators, kinases, and hormones; Vice-President Dewey, before the Section of Education, science as a method of thinking and science as information in education.

The meeting was marked by a series of joint meetings between sections of the association and corresponding affiliated societies. By virtue of a resolution adopted by the council at its April meeting, sectional committees arranged in almost every case one or more sessions of general interest, conducted under the auspices of the sectional officers, while programmes of papers of a strictly technical character and of interest limited to specialists were read under the auspices of the affiliated societies. This arrangement was particularly happy in the cases of Section A and the American Mathematical Society; Section B and the American Physical Society; Section C and the American Chemical Society; Section E and the Geological Society of America; Section F and the American Society of Zoologists; Section G and the Botanical Society of America; and Section H and the American Anthropological Association. Under Section K an important symposium on the subject of internal secretion was held, at which the following papers were presented:—A general review of the chemical aspect of internal secretion, by R. H. Chittenden; the internal secretion of the pancreas, by W. G. McCallum; our present knowledge of the thyroid function, by S. P. Beebe; metabolism after parathyroidectomy, by J. V. Cook; and physiological consequences of total and of partial hypophysectomy, by H. Cushing.

On Tuesday evening, December 28, a public lecture complimentary to the citizens of Boston was given by Dr. C. W. Stiles, of the United States Public Health and Marine Hospital Service, on the subject of the hookworm problem in the United States in reference to public health. This lecture, the subject of which is brought prominently into the public eye at this time on account of Mr. Rockefeller's gift of 1,000,000 dollars to be devoted to an effort to stamp out the hookworm in the south, was attended by a large audience.

On Thursday evening, December 30, an interesting lecture was given by Dr. John B. Smith, on the subject of insects and entomologists, their relation to the community at large.

On Wednesday evening, December 29, the Society of American Naturalists and the biologists in attendance at the meeting held their annual dinner, at which the address of the retiring president of the naturalists, Prof. T. H. Morgan, was given. His subject was "Chance or Purpose in the Evolution of Adaptation." The American Chemical Society gave its annual dinner on the Thursday evening. Other dinners of special organisations were scattered through the week.

At the meeting of the general committee, Minneapolis was chosen as the place of the next meeting, beginning December 27, 1910. The following officers were elected:—

President:—Prof. A. A. Michelson, University of Chicago. Vice-Presidents (or presidents of sections):—Section A, Prof. E. H. Moore, University of Chicago; Section B, Dr. E. B. Rosa, Bureau of Standards, Washington; Section C, Prof. G. B. Frankforter, University of Minnesota; Section D, Prof. A. L. Rotch, Blue Hill Observatory, Boston, Mass.; Section E, Dr. J. M. Clarke, State Geologist, Albany, N.Y.; Section F, Prof. J. Reighard, University of Michigan; Section G, Prof. R. A. Harper, University of Wisconsin; Section H, Prof. R. B. Dixon, Harvard University; Section I, Dr. T. E. Burton, Cleveland, Ohio; Section K, Prof. F. G. Novy, University of Michigan; Section L, the Hon. A. Ross Hill, president, University of Missouri. Secretary, Section I., Fred C. Croxton, Washington, D.C.; permanent secretary, Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.; general secretary, Prof. F. E. Clements, University of Minnesota; secretary of the council, Prof. J. Zeleny, University of Minnesota.

Grants were made to the Concilium Bibliographicum Zoologicum at Zürich, and to individuals as follows:—To Prof. T. D. A. Cockerell, to assist in an investigation of the microscopic structure of the scales of different genera of fishes; to Dr. W. D. Hoyt, to assist in an investigation upon environic relations of the alga Dictyota, which develops a rhythm in fruiting coincident with every alternate springtide; to Prof. G. J. Peirce, to assist in investigations of organisms inhabiting the alternately filling and drying salt-water pools along the coasts of central California. The last two grants are to be expended under the supervision of the standing committee upon the relation of plants to climate.

THE MEAN HEIGHT OF THE ANTARCTIC CONTINENT.

PROF. W. MEINARDUS gives the results of an estimate of the mean elevation of the central core of the Antarctic land mass, based on the distribution of atmospheric pressure and consequent exchange of air between the two hemispheres, in the November and December numbers of Petermann's *Mitteilungen*. Extending Spitaler's results with the help of Mohn's discussion of the *Fram* observations, and Baschin's maps of the southern oceans, Prof. Meinardus finds that, while the mean pressure (not reduced to sea-level) is 0·85 mm. higher in January than in July between latitudes 0° to 80° N., in the zone 0° to 50° S. it is 2·14 mm. lower. In higher southern latitudes, as far as 60° S. lat., the January pressure is 0·73 mm. less than the July, and from 60° S. to the Antarctic circle the relation is almost one of equality. Hence, allowing for proportional areas, it follows that within the Antarctic circle the true atmospheric pressure must be 11 mm. higher in January than in July.

Observation, however, has so far failed to reveal the existence of this excess; the diminution of the southward temperature gradient and consequent weakening of easterly winds on the edge of Antarctis in summer render it probable that, as in the north polar region, the pressure at sea-level is actually lower in summer than in winter. The discrepancy can be explained by assuming a mean elevation for the area within the Antarctic circle, and taking −3° and −26° as the mean temperatures for January and July respectively, Porf. Meinardus gets a value for this of 1328 metres, or, as a second approximation with temperatures −6° and −29°, 1350 metres, with a probable error of ± 150 metres. Having regard to the proportion of the area known to be covered by sea, the land surface is taken as 14 millions of square kilometres (Bruce and Krümmel), and its mean height then becomes 2000 metres, with a probable error of ±200 metres.

Recent explorations suggest that this value is not far from the truth, the covering of inland ice being, as in Greenland, an important factor. If it is approximately correct, Antarctica is the largest mass of raised land in the world; it is half as large again as Europe, and Asia, the highest of the known continents, has a mean elevation of less than half (950 metres). The accepted value of the mean height of the land surface of the world, 700 metres, is raised to 825 metres, and the mean level of the physical surface of the globe from 205 to 240 metres.

THE NATURAL HISTORY MUSEUM.

IN NATURE of December 16 and 30 we reprinted from the *Times* some letters dealing with this subject. We were under the impression that the main point of contention was the complete separation of the Natural History Museum from the other collections in the British Museum, as recommended by the Duke of Devonshire's Royal Commission in 1874, to go no further back.

Sir Archibald Geikie has since pointed out to us that the questions put to him in the letter from the Speaker of the House of Commons to which he replied "were entirely in reference to the relations between the Trustees and the Museum," and that, this being so, we should have given a letter from Mr. Carruthers dealing with this point which had also appeared in the *Times*. We therefore now reprint the letter in question:—

Sir,—The President of the Royal Society, Sir Archibald Geikie, has expressed clearly his view on the questions in relation to the administration of the British Museum recently raised in your columns. A former eminent President, Prof. Huxley, was brought by his experience as Trustee, as Sir Archibald has been, to similar favourable conclusions.

It was notorious that Prof. Huxley severely criticised the governing body of the Natural History Departments of the British Museum. He had expressed this view to me personally, but, after he had been some time a Trustee, he spontaneously informed me that he had totally changed his opinion, and that he could not imagine a more efficient system of administration. This, I must add, was previous to 1898.

As Keeper of Botany for twenty-four years, I cannot recall a single occasion in which my department suffered from the action of the Trustees. I always found them intelligent and sympathetic in the affairs of the department.

William Carruthers.

NOTES.

The council of the Royal Astronomical Society has awarded the gold medal of the society to Prof. F. Küstner, director of the University Observatory of Bonn, for his catalogue of stars, his pioneer determination of the aberration constant from motions in the line of sight, and his detection of the variation of latitude.

The Geological Society of London will this year award its medals and funds as follows:—Wollaston medal, to Prof. W. B. Scott; Murchison medal, to Prof. A. P. Coleman; Lyell medal, to Dr. A. Vaughan; Wollaston fund, to Mr. E. B. Bailey; Murchison fund, to Mr. J. W. Stather; Lyell fund, to Mr. F. R. Cowper Reed and Dr. R. Broom.

Prof. R. Meldola, F.R.S., has been elected an honorary member of the Sociedad Española de Fisica y Quimica.

Prof. W. Trabert has been appointed director of the k.k. Zentralanstalt für Meteorologie und Geodynamik at Vienna.

M. G. Eiffel has been elected president of the Meteorological Society of France for 1910, and M. Teisserenc de Bort and Dr. de Valcourt vice-presidents.

The death is announced, at the age of ninety-one years, of Dr. George Skene Keith, formerly a well-known Edinburgh physician. Dr. Keith was the author of the book "Plea for a Simpler Life," which had a wide circulation, and of other works.

By the will of the late Sir Alfred Jones, the sum of about 500,000*l*. will be at the disposal of the trustees "for such charitable purposes and objects in England (or any British possession on the west coast of Africa) as they may in their absolute discretion think fit." For the guidance of the trustees in the administration of this very comprehensive trust, Sir Alfred Jones made the following suggestions, among others, as to purposes to which it might be applied:—(*a*) the technical education of natives on the west coast of Africa; (*b*) the advancement, benefit, or support of education or science; (*c*) original research of all kinds into the cause of disease on the west coast of Africa.

Sir Ernest Shackleton has denied the rumour, to which reference was made in a note last week, that he is to lead this year a third expedition to the Antarctic. He discussed Antarctic exploration recently with a private party of geographical experts in Berlin, and on that occasion explained that, in the event of his going south again, he would travel polewards from the Weddell Sea or Gaussberg. The Weddell Sea was penetrated to 74° 15′ S. by Captain Weddell in 1823. The Gaussberg is a basalt mountain in Kaiser Wilhelm's Land, on the southern shore of the bay in which the *Gauss*, the vessel of the German Antarctic Expedition of 1901–3, reached its farthest south. Captain Scott proposes to establish his base near MacMurdo Sound, which was the winter quarters of the *Discovery*, and near which Sir Ernest Shackleton had his main base during the late expedition.

We learn from a note in the *Engineer* for January 7 that dirigible airship companies are moving fast in Germany. A Parseval airship was ordered this month by the Munich Aëronautical Company, the share capital of which is to be increased to 400,000 marks. The airship is expected to be delivered on May 1, when regular aërial tours are to be commenced. An airship station is to be built in the Upper Bavarian tourists' territory, to which flights will be made from Munich. Another aëronautical company has been founded this month for exploiting the motor-driven airships according to the system of Herr Zorn, and for establishing airship lines. The municipality of Gräfrath has placed about sixty-eight acres of ground at the disposal of this company. Major Von Parseval has accepted a nomination as unsalaried lecturer on dirigible airships at the Charlottenburg High School, and has already given one lecture before the teaching staff.

The next International Congress of Mining, Metallurgy, Applied Mechanics, and Practical Geology will be held at Düsseldorf in the last week of June next. The conference will be divided into four sections, dealing respectively with the subjects named in the title of the congress. The president of the mining section is Mr. Randebrock, director-general of the Gelsenkirchener Mining Company; of the metallurgical section, Mr. Springorum, director-general of the Hoesch Iron and Steel Works; of the applied mechanics section, Mr. C. Kiesselbach; and of the practical geology section, Mr. Schulz-Briesen. The general secretaries are Dr. Schrödter and Mr. Loewenstein. There will be two grades of membership of the congress: members, who are entitled to become patrons of the congress by payment of not less than 5*l*., and members who pay a subscription of 1*l*. Any inquiries should be addressed to the committee of organisation of the congress, Jacobistrasse 3/5, Düsseldorf, Germany. Members of the Iron and Steel Institute resident in the United Kingdom who wish to attend the congress are requested to apply to the institute not later than February 26.

During last week the Liverpool Geological Society celebrated the jubilee of its first meeting. On Monday, January 10, the society entertained at dinner the Lord Mayor and Lady Mayoress, and representatives of the University, of kindred societies in the city, and of the Yorkshire Geological Society and the North Staffordshire Field Club. The toast of the University elicited expressions of regret at the absence of a chair of geology in the University. The first meeting of the society having been held on January 11, 1860, an open meeting was held on the Tuesday of last week, and was largely attended. Mr. W. Hewitt, the president, was in the chair, and the minutes of the first meeting having been read, he remarked that that meeting was held in a room in the house of Mr. G. H. Morton, the first honorary secretary of the society. He also read a letter from Mr. H. Duckworth, the first president, congratulating the society and regretting that his age prevented his being present. Prof. J. W. Judd, C.B., F.R.S., an honorary member of the society, then delivered an address on "The Triumph of Evolution: a Retrospect of Fifty Years," remarking that the foundation of the society was nearly coincident with the appearance of Darwin's "Origin of Species." A very careful *résumé* of the address appeared in the Liverpool papers, and it is to be hoped that the address will later be printed *in extenso*.

The first and second annual reports presented by the council of the National Museum of Wales to the Court of Governors are now available. The second report deals with the year ending September 30 last, and records satisfactory progress in the work of founding and establishing the museum. The report points out that Dr. W. E. Hoyle, the director of the museum, entered upon his official duties on March 1. In August an advertisement was issued requesting designs to be sent in for a building to cost 250,000*l*. when complete, and it is hoped it may be found possible to erect about one-third of it in the first instance. The sum of 2000*l*. is included in the estimates of the Chancellor of the Exchequer for the current financial year to defray the working expenses of the museum, and of this 500*l*. has been received. The trustees of the "Cardiff Fund" have handed over the sum of 26,796*l*. which had been collected as a contribution to the building fund in the event of the museum being located in Cardiff. A Bill, promoted by the Cardiff Corporation, is before Parliament empowering the Corporation to make over to the National Museum the collections contained in the Welsh Museum of Natural History, Arts and Antiquities, belonging to the municipality, together with the proceeds of a halfpenny rate, which at the present time would yield about 2000*l*. per annum, towards the maintenance of the museum. In March last the director of the museum visited northern Germany and Scandinavia to study museums and kindred institutions with the view of acquiring information which will be needed in organising the new institution, and a report on the visit is printed as an addendum.

The *Journal of Conchology* for January contains a paper, by Mr. J. W. Vaughan, on the land and fresh-water molluscs of South Wales.

The *Entomologist's Monthly Magazine* for January opens with a coloured plate of seven rare or otherwise interesting British insects, of which one is a wasp, while the remaining six are beetles. The wasp, *Odynerus herricki*, was first recorded as British on the evidence of a single specimen in Dorsetshire in 1878; a second example was subsequently taken in Purbeck, and a third near Wareham, but in 1908 the species was found in abundance near Swanage.

In the report of the Madras Government Museum for 1908–9 it is announced that, at the time when the document was drafted, four volumes of Mr. Edgar Thurston's encyclopædic work on the "Castes and Tribes of Southern India" were then ready, and that it was hoped the printing of the remaining volumes would be completed during the current financial year. The museum has received a number of additions during the year, among which may be mentioned a series of coins acquired by means of the Indian Treasure Trove Act.

The value of the stereoscope in biological investigations forms the subject of an article, by Dr. W. Berndt, in *Naturwissenschaftliche Wochenschrift* of January 2. The instrument, it appears, has lately been used by Prof. F. E. Schulze, of the Berlin Zoological Institute, for the investigation of the structure and mode of action of the ultimate ramifications of the bronchial tubes, or broncheoli, in the lungs of mammals. Such objects have to be prepared in a special manner before being photographed for the stereoscope, but when this is done a stereogram is stated to afford an insight into the structure which cannot be obtained in any other way. Stereograms of an amœba, of the broncheoli of a rat's lung, and of a section of the lung of an ostrich illustrate the paper.

We are indebted to the author, Mr. J. W. Shoebotham, for a copy of his paper on the life-history of *Callidium violaceum*, reprinted from vol. iv., part iv., of the *Journal of Economic Biology*. In the year 1908 Mr. Shoebotham noticed insect-borings in some of the wooden fences near Berkhamsted, and subsequently ascertained that these were made by the larvæ of the beetle *Callidium violaceum*, a species which does not appear to have been observed in England as damaging timber since the time of the Rev. William Kirby. Mr. Shoebotham has worked out the life-history of this beetle, which attacks only coniferous timber —more especially larch—from which the bark has not been removed. The larvæ burrow between the bark and the wood, but subsequently tunnel into the latter, in which they pass the pupa-stage.

In the January number of Witherby's *British Birds* further notes are given with regard to the flights of crossbills which visited the British Islands in the second half of 1909. In Durham these birds were noticed in the last week of June, while at Woburn Abbey a flock was observed so late as December 24. As an appendix to these notes, Dr. C. B. Ticehurst refers to the circumstance that the crossing of the two halves of the beak in these birds is dimorphic, the upper half having its tip directed in some cases to the right and in others to the left side. In *Loxia curvirostra* the rights seem to be about equal in number to the lefts, but in *L. leucoptera* the lefts appear to be twice as numerous as the rights. Further specimens are, however, required before the existence of such a difference between the two species can be considered proven. In 1903 three examples of the black-winged pratincole (*Glareola melanoptera*) were shot in Kent, these being the first recorded British examples of the species. A fourth specimen was shot at Northallerton, Yorkshire, on August 17, 1909.

A description of the lateral roots of *Amyelon radicans*, a Carboniferous type now accepted as part of a gymnospermous Cordaitean structure, forms the subject of a paper, by Mr. T. G. B. Osborn, in the *Annals of Botany* (vol. xxiii., No. 92) with respect to the branching of the root and the occurrence of a fungus permeating the cells of the cortex. The fungus mycelium is traceable in the outer cortex, but only forms dense tufts in the inner zone; the hyphæ are non-septate, ending sometimes in thick-walled vesicles. Proceeding from analogy with the root-tubercles of Podocarpus, and having regard to the branching tendency of the lateral roots, the author arrives at the conclusion that the fungus was a mycorrhiza.

The Government of India has issued two additional Forest Pamphlets (Nos. 10 and 11) dealing with Indian timbers, prepared by Mr. R. S. Troup, the Imperial forest economist. The first refers to *Lagerstroemia tomentosa*, a tree, yielding Burmese Leza wood, that grows in the forests of Burma with *Xylia dolabriformis*. It might be classed with American birch, with which, however, it could not compete on the European market. It is recommended for use in India for tea-boxes, and is under trial for railway sleepers, as also for conversion into match splints. The second pamphlet deals with *Carallia integerrima*, which yields a timber resembling European oak in the silver grain, but differing in its brittle nature. Locally it is used in construction and for agricultural implements, and has been favourably reported on for brush-backs.

A paper on the British pansies, contributed by Dr. E. Drabble to the Journal of the Royal Horticultural Society (vol. xxxv., part ii.), is brought to notice, not only for the observations which are recorded, but also because it represents a line of work which is desirable and likely to be fruitful in results, especially in the case of plants which are hybridised. The author has taken the species *Viola tricolor*, L., and traced out by comparison with authentic specimens, as also by growing plants through several generations, a series of forms—the elementary species of Jordan and Boreau—among British plants. As a conclusion, four classes of British pansies are demarcated, and it is suggested that the garden stock may have been produced from *Viola Lloydii*, *V. variata*, and (rather doubtfully) *V. polychroma* by crossing with *V. lutea*.

When consideration is given to the great difference between the conditions in the Alps and in English gardens, it is a matter for surprise that so many Alpine plants can be grown successfully in our climate. The contrast is well brought out in an article published in the Journal of the Royal Horticultural Society (vol. xxxv., part ii.) by Mr. A. Clutton-Brock, who submits some arguments with respect to cultivation and treatment which cannot fail to interest the growers of alpines. Primarily, the author directs attention to the correct disposition of rocks and stones so that the roots may run underneath and obtain protection from drought. This is particularly necessary for Dryas, *Silene acaulis*, and *Polygala Chamaebaxas*. Top-dressing is suggested for Primula and *Aster alpinus* to imitate the action of deposits left by the snow. Close planting is another recommendation, provided unequal competition between intermingling plants can be avoided. On this point the author gives details regarding suitable combinations of plants.

From the *Agricultural Journal of British East Africa* we learn that cotton growing is making steady and continuous progress at the coast, although the early difficulties were very numerous, and large sums of money had to be expended in educational work. There is still the prospect of trouble with insect pests, but it is stated that cotton growing is distinctly profitable to the native. In the same journal there is also a suggestive article on the prospects of the production of cane sugar; considerable quantities are at present imported, but there is every reason to believe that it could be produced locally and form the basis of a flourishing industry.

We have received from the United States Department of Agriculture Bureau of Soils a bulletin, by Dr. Whitney, summarising the results of nearly 3000 manurial trials on cotton soils made during the past twenty-one years. The general conclusion is that complete fertilisers give the largest and, as a rule, the most profitable crop. The increase in yield due to mixtures of artificial manures was approximately an additive effect, an interesting result that deserves further examination. A report is also issued on the Volusia soils, which cover an area of more than ten million acres in southern New York, northern Pennsylvania, and north-eastern Ohio, and are commonly said to be "worn out," the farms in some localities having been abandoned. It is well illustrated and typical of the soil survey work carried out by the department. The soils suffer from lack of drainage, poor physical condition, and depletion of organic matter, conditions for which suitable remedies are suggested.

We have received advance chapters of the annual report on the mineral production of Canada during the calendar years 1907 and 1908, dealing respectively with the production of coal, coke and peat, of natural gas and petroleum, and of iron and steel in the Dominion. These reports show a steady but not a great development in all these branches of mineral industry; the production of coal in the two years in question was respectively 10,511,426 and 10,886,311 tons, as against 9,762,601 tons in 1906, about one-eighth of this being made into coke; the production of peat was practically nil. The production of crude petroleum was 788,872 barrels (of 35 gallons) in 1907 and 527,987 barrels in 1908; the production of natural gas was also important. The production of pig iron is about stationary, being 651,962 tons in 1907 and 630,835 tons in 1908, about one-sixth in each case being smelted from native and the remainder from imported ores.

Mr. R. A. Stewart Macalister, by permission of the committee of the Palestine Exploration Fund, for whom the materials were originally collected, contributes to the number of the Journal of the Gypsy-lore Society for October, 1909, the first of a series of papers on the language of the Nawar or Zutt, the nomad smiths of Palestine. The language is in its basis pure Romani, but it has assimilated many Arabic words, that is to say, not literary Arabic, but the colloquial dialect of Palestine. Some words are used without change, but a large number have become naturalised in Nuri, either indicating that they are survivals of a period when the tribe had newly arrived in Arabic-speaking lands, or that some terms have been modified with the object of secrecy to adapt them for use in the tribal argot. Mr. Macalister works out carefully the method of making these modifications. It is to be regretted that few of the stories so far published include any interesting or characteristic folk-lore material, most of the examples being incidents of everyday life or scraps of folk-tales dictated by the compiler.

An excellent general account, by Dr. H. R. Mill, of the rainfall of the British Isles in 1909, in relation to other years, is contained in the *Times* of January 14, based upon a preliminary study of some 2000 of the returns of the British Rainfall Organisation, and on a comparison of 100 long-established records, distributed as uniformly as possible over the country, with their own averages for 1870–99. These latter values are given in tabular form, and the summary of the percentages shows considerable differences in various divisions; in Scotland, as a whole, the annual rainfall was practically normal; in Ireland and Wales there was a deficiency of 5 per cent., in the north of England a considerable excess, while the amount over the British Isles generally was exactly the average. These results naturally agree in the main with those given by the Meteorological Office in its annual summary (Nature, January 6). The best idea of the difference of the annual rainfall of the year from the average is shown by a neat little map. This exhibits conspicuous dry areas in the extreme south-west of Ireland, Wales, and England, and in the north-west of Scotland. The distinctly wet regions, with more than 10 per cent. above the average, surround the south and east of Great Britain; another area with more than 10 per cent. was in Lincoln, the north-east of Yorkshire, and Lancashire. The wettest months, generally speaking, were March, April, October, and December. November was unquestionably the driest month; over the whole of England the rainfall was only one-third of the normal. Dr. Mill remarks that the year probably acquired its undeserved reputation for wetness from the chilly gloom of some of the summer months, which both looked and felt far wetter than they were.

Messrs. Teubner are issuing in pamphlet form some of the most important of the public addresses which have been delivered by distinguished German physicists during the last few years. Amongst them is one on electrons, given by Prof. W. Wien before the Versammlung deutscher Naturforscher, which has already reached a second edition. It deals in a clear and interesting way with the rise and progress of our knowledge of the properties of electrons, and explains the methods by means of which that knowledge has been acquired, without making a great demand on the reader's mathematical powers. Prof. Wien prefers the theory which makes an electron in motion take a spheroidal shape to that on which electrons are rigid spheres, and shows in his additions to the present edition that the evidence from the principle of relativity supports this view. A special difficulty of the electron theory is, in his opinion, that of explaining how an electron holds together under the enormous repulsive forces which the parts of it exert on each other.

The *Journal de Physique* for December, 1909, contains a paper communicated to the Société française de Physique on November 19 by M. L. Houllevigue, in which the sizes of the particles shot off from a silver kathode in a vacuum tube are calculated. The method depends on the fact that when a vapour condenses on a surface colder than itself the drops form at definite points of the surface constant in number, and if evaporated and re-condensed form again at the same points. When a glass surface has been exposed to bombardment from the kathode rays, the author considers that the points at which condensation of a vapour occurs are those at which particles of the kathode have become attached to the glass. The number of these points, and therefore of the kathode particles, is proportional to the time of exposure to the bombardment, and may be counted directly under the microscope after mercury vapour has condensed on them. The thickness of a deposit may then be found by Fizeau's method after the film has been exposed to the vapour of iodine. From the volume of the deposit on any area and the number of particles calculated from the counting experiment, M. Houllevigue finds the volume of the particle shot off from a silver kathode to be about 7×10^{-13} cubic millimetres, that is, it consists of about 20 million molecules.

For several years the Scottish Provident Institution, Edinburgh, has issued, within the covers of a blotter, an excellent set of star-maps, by Mr. W. B. Blaikie, showing the constellations visible when facing north and south month by month. The stars are represented by gilt asterisks on a dark blue background, upon which the names of the constellations are printed in black, so that when the charts are viewed at a suitable angle the stars are seen without the names, the result being very effective. With the 1910 issue (the thirteenth series), a chart of the heavens in two hemispheres is included showing the track of Halley's comet in 1909–10, and some notes upon the comet's orbit and spectacular appearance. The usual particulars of the positions of the sun, moon, and planets throughout the year are also given. The publication is excellently produced, and should continue its usefulness in promoting an intelligent interest in the aspects of the heavens and the movements of celestial bodies.

A VALUABLE paper on the testing of impulse water-wheels of the Pelton wheel type was presented by Mr. William Rankine Eckart at the Institution of Mechanical Engineers on January 7. This paper is of interest on account of the experiments described being the first of the kind on such a large scale. By means of the Pitot tube and other measuring devices the author has measured the nozzle discharge under different conditions, and so has determined the hydraulic efficiency of the generating plant, the capacity of each water-wheel amounting to about 3500 horse-power. The following table gives a summary of the more important results of the four tests made, and shows the distribution of the power as percentages of the power in the jet:—

Test number	1	2	3	4
Loss in bucket friction and eddies ...	23·0	23·2	27·7	29·2
Loss in residual velocity of discharge..	1·1	1·0	1·8	1·9
Other hydraulic losses	1·5	1·6	1·1	0·8
Loss in friction and windage, generator and wheels	7·5	4·4	3·2	2·8
Loss in generator, iron and armature..	2·8	1·8	1·3	1·2
Delivered to switchboard	64·1	68·0	64·9	64·1

IN the discussion on the hydraulic papers at the Institution of Mechanical Engineers on January 7, Dr. Unwin referred to the difficulties which Canadian engineers have to contend with in preventing stoppages from ice. Block ice is easily dealt with. With frazil ice, *i.e.* minute particles of ice suspended in and moving with the water, the difficulty is serious. We learn from a recent number of the *Canadian Engineer* that about forty water-wheels at and near Ottawa are now equipped with heating devices, which prevent frazil from stopping the wheels and clogging the gates and gate-mechanisms. The latest 3000-horse-power unit at the Ottawa and Hull Power and Manufacturing Company's Station has the chutes and gate chambers cored out, and there are pipe connections to the openings so that steam or hot water may be kept circulating through them when frazil is anticipated. The racks or screens are kept free from ice by electric motor-driven rakes, and at present none of these is heated. Mr. John Murphy recommends that the racks be submerged or otherwise protected from the atmosphere, when only a small amount of heat would be necessary to prevent ice clinging to them.

COMMENTING on the evidence offered at the inquiry into the cause of the disastrous fire at Messrs. Arding and Hobbs, Clapham Junction, the *Builder* for January 8 finds itself unable to agree with the architect's—Mr. Thorneycroft—opinions regarding his belief in the merits of steel as a structural material. Evidently he does not consider reinforced concrete to be a practical substitute for steel. It is, of course, understood that there are difficulties in altering and enlarging old buildings which prevent the changing of the general nature of the construction. Other evidence showed that, had there been concrete floors, and if the steel-work had been encased in concrete, there would have been little to burn except the contents of the rooms. As it was, the girders were only protected by the matched lining, and the distortion of the steel brought the building down. However strongly one may disapprove such methods of construction, the fact remains that the Clapham Junction building conformed with the requirements of the law, and represented quite an ordinary risk. Under the new regulations of the County Council protected steel-frame or reinforced concrete buildings ought to cost no more than structures of brick and unprotected steel. The extreme undesirability of the latter type is the most important lesson of this fire.

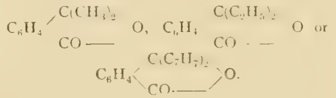
ON account of its fundamental importance in atomic-weight determinations, numerous researches have been published during the last four years on the atomic weight of chlorine, in most of which the direct ratio H/Cl has been attempted by gas volumetric or gas density methods. The latest contribution to this subject is by Otto Scheuer, who, in the current number of the *Zeitschrift für physikalische Chemie*, finds the weight of a litre of hydrochloric acid to be 1·6394 under normal conditions. From this the figure 35·466 is deduced as the atomic weight of chlorine, differing from the 35·460 of Gray and Burt by about 1 part in 6000. The paper in the *Zeitschrift* gives full details of the experimental work, and also of the methods of reduction employed. A critical examination of the results of Gray and Burt is given at the end of the paper.

THE place of honour in the *Bulletin de la Société d'Encouragement pour l'Industrie nationale* for November, 1909, is given to a study, by MM. Pipereaut and Vila, on the manufacture of zinc sulphide and its use as a pigment. From a report by M. A. Livache, which precedes the memoir, it appears that a law has just been passed prohibiting entirely the use of white lead as a paint after the expiry of a period of five years, and that the authors have devised a satisfactory method of preparing zinc sulphide, as a substitute, by dissolving the oxide in caustic alkali and boiling the solution with sulphur, the first portion of which throws down the impurities (lead and other metals giving coloured sulphides), whilst the later additions precipitate the zinc sulphide in a pure form which (after drying at a red heat) is eminently suited for use as a paint.

THE monographs on photo-chemistry by Prof. Bancroft, which have been appearing in recent numbers of the *Journal of Physical Chemistry*, have been followed up by two experimental papers, one of which, by Mr. G. A. Perley, on solarisation, appears in the November number, and the other, by Mr. J. W. Wilkinson, on the phosphorescence of some inorganic salts, in the December number of 1909. The latter contains an interesting account of some luminous effects produced during the electrolytic preparation of insoluble metallic salts, and during slow oxidation, chlorination, &c. In a large range of cases it is shown that the colour of the light emitted is identical with that which is produced when the salt is made to phosphoresce by various methods, and the view is advanced that the phosphorescence is due to certain definite types of chemical change.

The *Journal of Physical Chemistry* for November, 1909, contains a paper, by Mr. B. E. Curry, on the alloys of zinc with antimony, tin, cadmium, bismuth, and lead. Although the metal forms two layers with lead and with bismuth at low temperatures, the mutual solubility increases rapidly as the temperature is raised, the lead-zinc alloys becoming completely homogeneous at about 920° and the bismuth-zinc alloys at 820°. The formation of compounds was observed only in the alloys of zinc and antimony, which gave crystals of $ZnSb$ and Zn_3Sb_2, but solid solutions were obtained of zinc in tin (up to 7 per cent. Zn), in bismuth (up to 4 per cent. Zn), and in cadmium (up to 4 per cent. Zn), and of cadmium in zinc (up to 4 per cent. Cd); the zinc-antimony alloys also gave three series of solid solutions, resulting in a very complex equilibrium diagram.

The Journal of the College of Science, Tokyo, of June 15, 1909, which has recently come to hand, contains a paper, by Y. Shibata, on the action of the Grignard reagent on *o*-phthalic esters. The *p*-phthalic esters have been shown by Ullmann and Schaepfer to resemble the succinic esters in giving glycols of the type $C_6H_4\left<\begin{matrix}CR_2.OH\\CR_2.OH\end{matrix}\right.$, but the main product from the *o*-esters is a phthalide such as



$$C_6H_4\left<\begin{matrix}C(CH_3)_2\\CO\text{——}\end{matrix}\right>O,\quad C_6H_4\left<\begin{matrix}C(C_2H_5)_2\\CO\text{——}\end{matrix}\right>O \text{ or } C_6H_4\left<\begin{matrix}C(C_7H_7)_2\\CO.\text{——}\end{matrix}\right>O.$$

The action may, however, proceed further, giving rise to the compounds

$$C_6H_4\left<\begin{matrix}C(CH_3)_2\\C(:CH_2)\end{matrix}\right>O \text{ and } C_6H_4\left<\begin{matrix}C(CH_2.C_6H_5)_2\\C(:CH.C_6H_5)\end{matrix}\right>O.$$

A remarkable compound of the second group is obtained by the action of phenyl magnesium bromide. It is formulated as $C_6H_4\left<\begin{matrix}C(C_6H_5)_2\\C(:C_6H_4)\end{matrix}\right>O$, but must be regarded as containing a trimethylene or "carone" ring in the group $=C\;C_6H_4$.

Mr. P. D. Malloch, of Perth, is publishing through Messrs. A. and C. Black a book on the "Life-history and Habits of the Salmon, Sea-trout, Trout, and other Freshwater Fish." From his connection with the Tay Salmon Fisheries Co., the author has had unusual opportunities of studying the subject, and has been able to clear up many doubtful points by the marking of smolts and their recapture as grilse and salmon. The study of scales also forms a section of the book.

M. Ch. Delagrave, of Paris, has sent us a copy of "La Langue Internationale et la Science," which is published at the price of one franc. This volume is a French translation of a book reviewed in these columns on August 19 last (vol. lxxxi., p. 218), "Weltsprache und Wissenschaft. Gedanken über die Einführung der internationalen Hilfsprache in die Wissenschaft," by Profs. L. Couturat, O. Jespersen, R. Lorenz, W. Ostwald, and L. Pfaundler. The translation has been done by M. Boubier, of the University of Geneva.

The issue of Willing's "Press Guide and Advertiser's Directory and Handbook" for 1910 (price 1*s.*) has reached us. It continues to be what its subtitle claims for it—a concise and comprehensive index to the Press of the United Kingdom. It provides information concerning all the newspapers, magazines, reviews, and other periodicals, including journals, proceedings, reports, and transactions of learned societies. Lists of the principal colonial and foreign journals are also included.

The 1910 issue of "The Science Year Book," edited by Major B. F. S. Baden-Powell, and published by Messrs. King, Sell and Olding, Ltd., at 5*s.* net, includes several new features. The volume contains a monthly astronomical ephemeris which should be of particular service to astronomers and other observers, many useful tables, star-maps for the four seasons, with key-charts showing the names of constellations visible, a brief summary of matters of scientific interest in 1909, a glossary of recently introduced scientific names and terms, a full list of learned societies with particulars of membership, and a short account of various prizes and awards for scientific research. A good portrait of Sir Archibald Geikie, K.C.B., forms a frontispiece to the volume, and there is a chart showing the track of Halley's comet during 1910. The remainder of the volume consists chiefly of a diary, with a page for each day, and having at the head columns for the insertion of maximum and minimum temperatures, barometric height, rainfall, and other results of meteorological observation. The volume provides observers with exactly the kind of tabular information frequently required; and, with the diary, it constitutes a year-book which merits a place upon the study tables of many men of science and the bookshelves of observatories.

OUR ASTRONOMICAL COLUMN.

Discovery of a New Comet.—Telegrams from the Kiel Centralstelle announce the discovery of a new comet at Johannesburg on January 17. In the first it was stated that the comet was discovered by Mr. Drake, and was seen at and after sunrise. Its approximate position was given as five or ten degrees south-south-west of the sun, which it was approaching.

The second telegram gives the more exact position, at 21h. 21·5 m. January 16 (Johannesburg M.T.), as

R.A. 19h. 50m. 28s., $\delta = 25^\circ\ 0'$ S.,

and states that the daily motion is +16m. 32s. in R.A. and $-2^\circ\ 25'$ in N.P.D.

As this object is intensely bright as it was seen in sunshine, and is travelling northwards, we may expect a fine display after sunset during the present week.

Halley's Comet.—A telegram from Messrs. Frost and Parkhurst, dated December 31, 1909, and published in No. 4381 of the *Astronomische Nachrichten*, states that the prismatic camera shows the light of Halley's comet to be now largely due to the third cyanogen band. This suggests that attempts to photograph the comet should now be made with quartz objectives or speculum reflectors. Both glass objectives and silver-on-glass mirrors absorb a large percentage of the ultra-violet radiations, and the difficulty of obtaining quartz lenses of large aperture may possibly be compensated for by the much greater transparency of quartz, as compared with glass, to the more refrangible rays.

The anomalous apparent brightening of the comet which occurred in November has not been continued, and until about the middle of March the distance between the comet and the earth will continuously increase; but it is thought that the development of the comet, as it approaches nearer to the sun, should be sufficient to make naked-eye observations possible by about the end of February.

This anomalous increase of the apparent brightness is described by the Rev. T. E. R. Phillips in a note appearing in No. 2, vol. lxx., of the Monthly Notices. He commenced observing, with a 12¼-inch Calver reflector, on November 16, and observed the apparent brightness on ten nights between that date and December 8; from these observations he concludes that the apparent brightness of the comet was unquestionably greatest on November 22, when he was able to see it with the aperture stopped down to 3½ inches. The next night, under comparable atmospheric conditions, it was quite inconspicuous even with the full aperture. Again, on December 6, with a very clear and transparent sky, he was unable to see the comet with the aperture at $4\frac{1}{2}$ inches, and he estimates that its magnitude was not greater than 11·5 or 12·0; but on December 8 it was again brighter, the magnitude being estimated to be about 10·5 or 11·0.

On January 28·1 the comet will be in conjunction with, and 3° 48′ north of, Saturn; its conjunction with Mars occurred on January 15, when the actual distance separating the two bodies, about 37 million miles, was at its minimum value.

In a letter to the *Times* of January 14, the Earl of Crawford points out that for ages the sudden appearance of a great comet has been held to herald some great disaster or revolution. This view of the matter may still appeal to the native races of such countries as Morocco, Egypt, or India, where considerable unrest already prevails, and might be used by fanatical agitators to stir up further trouble. He suggests that the communication of a series of popular articles, written in the vernacular, to the native Press, might be beneficial. By announcing and welcoming the appearance of the comet, such articles would forestall the potential mischief-makers and render futile their possible announcements of supernatural manifestations.

The Spectra of Comets' Tails.—The observations of Deslandres, Evershed, Chrétien and others showed that in the spectra of the tails of Daniel's and Morehouse's comets there were certain radiations which were feeble in the heads but extended to considerable distances in the tails of those comets; the wave-lengths of the three strongest bands were about 402, 426, and 455, but no terrestrial origin could be found for them.

This has now been done by Prof. A. Fowler, who has succeeded in reproducing them terrestrially in the spectrum of the glow from vacuum tubes which were known to contain carbon compounds at extremely low pressures, 0·01 mm. or less. Further experiments are necessary to determine what particular form, or compound, of carbon is involved, but from the wave-lengths and the reproductions of the spectra published in No. 2, vol. lxx., of the Monthly Notices there can be no doubt that Prof. Fowler has succeeded in reproducing, in his laboratory, the conditions which obtained in the tails of the two comets mentioned above.

Two Curiously Similar Spectroscopic Binaries.—When Messrs. Plaskett and Harper, of the Ottawa Observatory, published the determined orbit of the spectroscopic binary ι Orionis, the apparent presence of a secondary disturbance was not discussed, because the lines of the spectrum are too diffuse to justify any final conclusions; but the recent determination of the orbit of another binary, B.D. − 1°·1004, showed that a similar case of secondary disturbance appeared there, and it was deemed desirable to make refined least-square solutions for both orbits.

The results show that the two binaries are remarkably alike. Both are in Orion, within 5° of each other, and both are helium stars; the periods are 29·136 and 27·160 days respectively, and the eccentricity of both orbits is abnormally high (0·74 and 0·76) for spectroscopic binaries. Other features are also very similar, but the most striking similarity is in the secondary disturbances, which are almost identical in period, amplitude, and phase. The period of the secondary in each case is the same as the period of the primary, a novel feature in spectroscopic binaries. It seems probable that the same physical cause is operative in both cases, but what it is is difficult to say; the orbital revolution of the system, produced possibly by a resisting medium or by tidal action, is tentatively suggested (*Astrophysical Journal*, vol. xxx., No. 5, p. 373).

The "Annuaire Astronomique," Belgium.—The "Annuaire Astronomique," for 1910, of the Royal Observatory of Belgium contains, besides the usual tables, ephemerides, &c., a number of useful notes and diagrams; among the latter is a coloured chart showing the official standard times of various countries. A list of observatories is also given, and special articles are contributed by various members of the staff of Uccle Observatory.

THE EVOLUTION OF THE BRAIN.[1]

As the result of the investigations carried on in the Museum of the Royal College of Surgeons during the last seventy-five years by its conservators and those who have drawn their inspiration, directly or indirectly, from the work done in the museum, it has become possible to establish on a firm basis the criteria for instituting exact comparisons of the structure of the brain in the various groups of Vertebrata.

This analytical work has now been carried far enough to justify us in attempting a synthesis of our knowledge of the evolution of the cerebral cortex. The special aim of such a research is to investigate the nature of the factors and the circumstances which have brought into being the neopallium, the part of the nervous system which, more than any other, is responsible for the kaleidoscopic manifestations of psychical activities, and the possession of which has made the Mammalia what they are, and given them the dominant position in the animal kingdom.

At the very root of the Vertebrata we find that Petromyzon has a cerebral hemisphere no larger than the olfactory bulb of which it is little more than an appendage. Direct nerve tracts pour smell-impressions into almost every part of the surface of this hemisphere. The cerebrum at its commencement is thus almost purely an instrument for the reception and the conscious appreciation of stimuli evoked by odoriferous particles, and, in the second place, for providing the means whereby the physiological processes underlying this state of consciousness may affect the rest of the nervous system, and through it influence the behaviour of the lamprey itself. It is just possible that even in this lowly vertebrate gustatory fibres brought up to the lobus inferior (of the fore-brain) from the terminal nuclei of the seventh and ninth nerves may make their way into the primitive cerebral hemisphere, but it is still uncertain whether the lobus inferior itself may not be the place where impressions of smell and taste meet.

Even in Petromyzon there is some indication of a differentiation of the hemisphere into a superficial cortical layer (tuberculum olfactorium) and a deeper ganglionic part (corpus striatum), and there is also some slight trace at the extreme dorso-mesial edge of the presence of a small rudiment of the pallium. The tuberculum olfactorium in the Selachii assumes a definite cortex-like arrangement of cells, and is now recognisable as one of the receptive apparatus for olfactory impulses coming directly from the olfactory bulb. The corpus striatum does not receive any direct olfactory fibres; it is the part of the hemisphere which receives afferent fibres from the tuberculum olfactorium, and possibly also from more caudally situated regions of the brain—almost certainly gustatory fibres from the lobus inferior—and it emits efferent fibres, which pass to the hypothalamus and indirectly influence the executive mechanisms of the body, *i.e.* its functions find expression in the behaviour of the animal.

In some of the Selachii the dorsal part of the hemisphere is definitely transformed into a cortical area or formatio pallialis. In Petromyzon there is still room for doubt as to the existence of any such structure, but when we turn to the study of the brain in some of the sharks there can be no doubt of the existence of a considerable area of primordial pallium. There is every reason to believe that this pallial formation represents the undifferentiated rudiment of the *whole* pallium of the higher vertebrates. Its mesial edge ultimately becomes specialised to form the hippocampus, which in the higher Vertebrata does not receive smell-impulses directly from the olfactory bulb, but indirectly through the intermediation of the olfactory peduncle and tuberculum olfactorium on the mesial side, and of the pyriform on the lateral side. The lateral edge of the pallium eventually develops into the pyriform lobe, which continues to receive olfactory impressions direct from the bulb. Much later on, only, in fact, when the mammal appears on the scene, the pallial area intervening between the hippocampus and the pyriform lobe becomes specialised to form the neopallium. It is only right to say that this view of the nature of the primitive pallium differs fundamentally from the various interpretations now being urged by other biologists.

---

[1] Summary of Three "Arris and Gale Lectures" on "Some Problems relating to the Evolution of the Brain," delivered in the Royal College of Surgeons on December 13, 15, and 17, 1909, by Prof. G. Elliot Smith F.R.S.

Putting aside the condition of affairs found in all other Ichthyopsida, the consideration of which would be confusing unless there were time to discuss their morphology in some detail, let us look for a moment at the brain of the Dipnoi. In the mud-fish the cortex-like material forming the tuberculum olfactorium becomes highly specialised, and forms a relatively enormous organ upon the basal aspect of the cerebral hemisphere, of which it constitutes more than half the bulk. The pallial formation also becomes more distinctly differentiated into a cortex, the lateral part of which can now be justly termed "pyriform" and the mesial "hippocampal." The fornix-fibres connected with the latter are embedded in a mass of ganglionic matter—the paraterminal body—which exhibits a functional relationship to the hippocampus analogous to that which the striate body presents to the other cortical areas. In other words, it is a nucleus of origin for large numbers of projection fibres which pass down to the hypothalamic region, and the cells of origin of these fibres are probably under the influence both of descending hippocampal (smell) fibres and ascending tracts from the lobus inferior of the hypothalamus (probably taste).

Leaving the Amphibia out of account, and turning at one step from the Dipnoi directly to the reptiles, it will be found that the highly developed tuberculum olfactorium of the Dipnoi has undergone a great diminution in size and an even more pronounced deterioration in structure, but the corpus striatum and the pallial formation show a great advance both in size and in specialisation of structure.

There are very definite reasons for rejecting the views of Ramon y Cajal as to the homology of the mesial wall of the reptilian hemisphere, and also von Kupffer's identification of the hippocampus. Nor can we accept in its entirety the interpretation of the limits of the hippocampal formation and of its constituent parts favoured by Edinger and Ariëns-Kappers.

The hippocampal formation of the reptile is *not* broken up into two parts, fascia dentata and hippocampus *sensu stricto*, as it is in the mammal, but is a continuous column of cells, as the lecturer pointed out in 1895—an opinion since confirmed by Giuseppe Levi.

But there is no fully differentiated fascia dentata in reptiles as Levi believes. The hippocampal formation of a lizard contains cells analogous to those of the fascia dentata *intermingled with* others like those of the hippocampus *sensu stricto*, and others, again, intermediate in structure between the two. Thus in the reptile the hippocampal formation is caught, as it were, in the act of differentiating. Ultimately (in mammals) all the hippocampal cells vanish from its mesial part, leaving only "dentate" cells, which form a receptive organ for incoming olfactory impulses, and the lateral (dorsal) part of the formation loses all its "dentate" cells and becomes a purely associative and projection-organ.

In reptiles, the larger size of the corpus striatum and pallial formation is probably related to the fact that many sensory fibres ascending from the optic thalamus make their way into the hemisphere. The researches of Edinger, Wallenberg, Gordon Holmes, Ariëns-Kappers and others, have made it appear most likely that these fibres carry tactile impressions from the tongue and the cutaneous areas around the mouth, and possibly also visual impulses.

These two categories of fibres are certainly abundant in the peculiarly aberrant and highly specialised brain of the bird, in which the corpus striatum takes on an enormously enhanced importance and significance, and develops along lines which diverge widely from the stream of mammalian evolution.

In the reptile there is no true neopallium, but great confusion in the relations is produced, because the lateral part of the pallial formation is being suddenly stimulated to expand by the entry of these sensory, and perhaps visual, fibres. The rapidly overgrowing cortex becomes bent into the ventricular cavity to form a pseudo-ganglionic (but really cortical) mass, which Edinger has called Epistriatum.

In the immediate ancestors of mammals the number and variety of sensory paths which found admission into the cerebrum became enormously increased, and led to a further specialisation of the pallial formation, resulting in the birth of the neopallium—a cortical area where all the sensory impulses brought to the cerebral hemisphere along these new channels might be received, be blended in consciousness with those coming from other sense-organs, and leave impressions which might be stored, as it were, in this neopallium, and so influence other sensations and states of consciousness at some subsequent time. The neopallium is thus the organ of associative memory.

It is, perhaps, not devoid of significance that the first appearance of a definite neopallium coincides with the transformation of the skin over the whole surface of the body into a highly specialised tactile organ.

The further evolution of the neopallium in the Mammalia, and the formation of sulci and convolutions, was also discussed, special stress being laid upon the value of the unrivalled collection of brains in the college museum for the study of this aspect of the subject.

CONFERENCES ON SCIENCE AND MATHEMATICS IN SCHOOLS.

THE Mathematical Association and the Public Schools Science Masters joined forces at their annual meetings held this month at Westminster School. We print below a programme of the proceedings, and attempt to indicate the present situation of science and mathematical teaching in relation to the work of these associations, following lines of thought prompted by the expression of opinion at the meetings.

We must first discriminate between the Mathematical Society and the Mathematical Association. The former body is devoted to research, the latter to the improvement of elementary mathematical teaching. The organ of the association is the *Mathematical Gazette*; one hears complaints that disproportionate space is given in its columns to problems of purely mathematical interest or to minutiæ, while the clamant need for reconsidering the bases of one of the fundamental branches of education remains unsatisfied.

In the course of a vigorous presidential address, Prof. Turner spoke of the reign of efficiency established in the department of Egyptian service under Captain Lyons. For responsible work of varied nature Captain Lyons selected able mathematicians from Oxford and Cambridge. These men proved successful, and Prof. Turner directed attention to this fact in support of his opinion that it is a mistake to strive after a "general education" for all boys. A gardener might as well treat his flowers as cabbages. In the paper which followed, Mr. Godfrey emphasised the importance of paying regard to the different requirements of students. The precise value of algebra in education deserved greater consideration. The remaining papers hardly provided such nutrient fare as one would wish for on an occasion when masters and mistresses from schools all over the country are summoned for annual conference. In the afternoon, however, a crowded meeting discussed the urgent problem of how to correlate mathematical and science teaching, an important report serving as the basis of debate. The committee responsible for the report consisted of six representatives of mathematical teaching, six of science, and two head-masters of preparatory schools. They had been asked to consider the possibility of correlating the teaching of mathematics and science, and their reply took the effective form of a series of recommendations for putting such correlation into practice. As might be expected from the composition of the committee, all the recommendations were evidently the outcome of practical experience in the class-room. The prime necessity was cooperation between the teachers of the respective branches, and it was recognised that the chief obstacle was the lack of laboratory training, which was, unfortunately, so common amongst mathematicians. To aid in removing this obstacle, an appendix was devoted to the vacation course in practical work organised for schoolmasters at the Cavendish Laboratory; the course was given last August, and is to be repeated next summer.

Many of the recommendations are commendable, *e.g.* that the practical measurements should have a real connection, not only with the ordinary arithmetical lessons, but also with the actual details of daily life. Nevertheless the general impression conveyed is disappointing. A prefatory memorandum warns the reader that the committee regarded as outside its purview the discussion of the functions of science and mathematics in a balanced education. This estimate of its duties appears to account for the limited view which detracts from some portions of their work. We recognise the right of the committee to formulate opinions directly contravening the principles of Prof. Perry, but it should be made clear that the committee has considered the methods advocated by men of no little experience and judgment with whom it disagrees. Again, there is a half-heartedness in some of the proposals which suggests that the committee has not yet advanced to the position taken by leading writers more than twenty years ago. For example, no reference whatever is made to graphs, and the official dictum of the Mathematical Association still stands "that it is undesirable (at the preparatory stage) to lay stress on the *practical employment* of graphs in solving equations or other problems." [The italics are in the original, *vide* Reports of the Committee of the M.A., p. 29 of the 1908 issue.]

The discussion was preceded by an eloquent benedictory address from Prof. Forsyth. He quoted Faraday's advice to Tyndall to work out any experimental result so far as possible, "so that the mathematicians may be able to take it up." Much good would accrue to the training of schoolboys if scientific results could be so left that mathematicians, even mathematical schoolboys, could "take them up." Prof. Forsyth also quoted from the regulations for the Mathematical Tripos to show that settled thought at Cambridge is in harmony with the spirit which animated the joint committee whose report was before the meeting. He pleaded for patience in early years of growth—"go gently, and you will go safely; go safely, and you will go far." It was plain from the speeches of Mr. Godfrey and Mr. Jackson that the committee had exercised much restraint, and that it had deliberately erred on the side of caution in the changes which were recommended.

Sir J. J. Thomson said exactly what was wanted. He amused the meeting by his description of the student at Cambridge who wanted a kind of physics that would not give a headache to a caterpillar, and of the delight and surprise of the mathematician at finding in the laboratory that the formulæ on which he had been working for many years bore some approximation to truth. He hoped the effect of the report would be to increase the belief of mathematicians in applied mathematics. In schools, mathematics and physics should go together almost from the beginning. It was necessary to make men believe in their mathematics. Was it necessary that mathematical masters should teach so little mathematics?

We have dwelt upon some of the weak points because, in our view, the present condition of mathematical teaching in schools calls loudly for reform, in which the Mathematical Association should take the lead. But it would be utterly unfair and untrue to describe either the report or the meeting as less than a success. Prof. Forsyth paid a well-merited tribute to the committee for the careful inquiries it had instituted and carried to completion, and for the practical character of its proposals. The meeting was crowded, and there was no hint of opposition to the work of correlation. The following resolution was passed without dissent and with heartiness:—"That this meeting is in sympathy with the attempt embodied in the present report to correlate more closely the teaching of mathematics and science."

The principal feature of the Science Masters' meeting was the president's address, entitled "The Future of Science in our Schools—their Complete Re-organisation a Necessity." Prof. Armstrong said that the men most competent to take charge of the schools in the future would be the science masters, it being their business to study method and to be practical, therefore to solve problems and to lead. Referring to compulsory Greek, he declared that Oxford insists upon lowering the moral tone of entrants upon university life by enforcing a test which is known to be farcical and futile, known to be one which spoils young lives in preparatory schools; and doctors of divinity in charge of our schools smile blandly at such proceedings.

The teaching of science in our schools should consist primarily of instruction in the art of inquiry. Our failure to make science teaching effective is due to a misunderstanding of what an experiment is. To speak of *showing* an experiment is a negation of terms—actually, a demonstration is given. Moreover, we begin too late; the child's desire to observe and experiment, to reason on the basis of observations made and from the results of experimental inquiry, must be fostered in every way. Mr. Lyttelton, in "Schools and Schoolboys," proposes that there should be no "science proper" in the earlier years of school life. "My contention," said Prof. Armstrong, "is that there should be little else than *proper science*; but then my definition of science is 'the business of knowing.'"

In order to develop the right attitude of mind in our pupils, we must despecialise our science teaching as well as our curriculum as a whole. Work must begin with practical arithmetic, dealing with materials of natural origin and ready to hand. The natural history of the garden pebble may provide the first steps in geology, physiography, and physics. When common materials have been studied—mainly from the physical point of view—it will be time to lay the foundations of chemical belief, and the rusting of iron (leading to combustion) and the study of limestone (leading to acidic and alkylic oxides) provide a good approach. The conception of structure should be developed by the thorough study of alcohol (leading to food and its functions). Plant life, and, later, human anatomy, should be studied, nor should Darwin's work be neglected. Every person of intelligence must be able to appreciate common natural objects and phenomena. Since the work must be done by the boys themselves, a revolution in school procedure will be needed, and science masters should be revolutionaries.

Our space does not admit further excerpts from this comprehensive address. We endorse many, but not all, of Prof. Armstrong's opinions; we give him credit for rendering to the association the service most needed at the present hour. Nothing can better promote educational efficiency than to force schoolmasters into a position of preparedness to give a considered judgment upon the *broader issues* involved in the organisation of curricula and methods—what to teach, why to teach it, and how. If teachers cannot become professionally articulate, these questions will be decided by amateur or professional organisers without their guidance and with disastrous national results.

The programme of the meetings was as follows:—

January 12, Mathematical Association:—President's address, by Prof. H. H. Turner; (2) Mr. C. Godfrey on different methods of teaching algebra for different classes of students; (3) Prof. P. J. Harding on elliptic trammels and Fagnano points; (4) Mr. W. J. Dobbs on an inexpensive balance; (5) Rev. J. J. Milne on the geometric interpretation of homographic equations and their application to loci; (6) Mr. T. J. Garstang on alternatives to Euclid's parallel postulate.

Mathematical and Science Masters' joint meeting:—(1) Address from the chair by Prof. Forsyth; (2) report on correlation of mathematical and science teaching, presented by Mr. C. Godfrey and Mr. D. Berridge.

January 13, Science Masters' Association:—(1) President's address, by Prof. H. E. Armstrong; (2) Mr. J. R. Eccles on simplification of symbols in physics text-books; (3) Mr. L. Cumming on advisability of teaching all boys the elements of geology and biology; (4) Mr. W. E. Cross on laboratory equipment and design; (5) Mr. F. M. Oldham on the teaching of oxidation and reduction.

There was an exhibition of apparatus and books. The apparatus of leading firms displayed steady improvement in working qualities, and received considerable attention. Sir E. Ray Lankester is the president-elect for the year 1911.

G. F. D.

NORTH OF ENGLAND EDUCATION CONFERENCE.

THE conference which met on January 6–8 in the buildings of the University of Leeds, under the presidency of Sir Nathan Bodington, Vice-Chancellor of the University, was the eighth of a series of meetings which have been annually convened in the larger centres of the north of England. There was a large attendance of teachers, administrators, and members of education committees, the total falling little short of 2000 persons. The publishers' exhibition in connection with the conference was frequented throughout each day, and the papers which were read were followed with interest by large audiences, and gave rise to a number of animated discussions.

Prof. Sadler opened on the morning of January 7 with an examination of "The Relation of Elementary Schools to Technical Schools, Day and Evening." An abridgment of his paper appeared in NATURE of January 13, so it is unnecessary to make more than a brief reference to it here.

Some of the chief difficulties in the way of further education for children from primary schools were traced by Prof. Sadler to the snapping by the factories of the educational tradition associated with the old apprenticeship system. Too many English parents now think that a child's education ends when he leaves the elementary day school, while our employers and foremen have lost the sense of responsibility for the further education of the young people in their employment. Substantial reform can only be attained after a completion of the change in public opinion now in progress, and by the re-enlistment of the great employers to the cause of continued education. As regards the legislative measures that will eventually be required to extend the powers of local authorities in dealing with technical continuation classes, and to secure regularity of attendance, Prof. Sadler advocated the recommendations of the Consultative Committee of the Board of Education.

Mr. James Baker contributed to this discussion an account of the system of continuation schools in Austria, from which it appears that apprentices to a great variety of trades are bound to attend regularly the industrial schools of their townships after leaving the elementary schools at the age of fourteen, and that employers are bound to allow the necessary time for such attendance.

Mr. J. H. Reynolds urged that the half-time system demanded by employers must be postponed until after the children's fourteenth year.

On Friday afternoon, January 7, Mr. Max Muspratt, J.P., C.C., opened the discussion on cooperation between employers and education authorities. He cited (as Prof. Sadler had also done) the example of certain large firms (Messrs. Brunner, Mond and Co., Northwich; Messrs. Lever Brothers, Port Sunlight; and the United Alkali Co., Widnes) the directors of which bound all their young employees to attend evening classes up to the age of eighteen or nineteen, the firms paying the fees. This system of friendly compulsion is rendered possible by the fact that the large works in question practically monopolise the labour market in their respective areas; but in the larger towns, owing to the difficulty of bringing the hundreds of offices and firms into line, the only solution is to give powers to local authorities to start some form of compulsory attendance at evening schools up to the age of sixteen for office boys and apprentices. In Liverpool the big engineering shops, *e.g.* of the Dock Board and the White Star and Cunard lines, offer a variety of inducements to apprentices to continue their education, and a similar beginning has been made in a variety of other trades (building, painting, plumbing, &c.).

Mr. V. A. Mundella described the scheme under which the Associations of Shipbuilders and Engineers of Sunderland cooperate with the Sunderland Technical College in the training of engineering apprentices.

Mr. R. Wallace, of the Wallsend Shipway and Engineering Company, and vice-chairman of the Wallsend Education Committee, said that any attempt to educate the masses beyond their capabilities would not benefit them, and would be a waste of the nation's resources. They were dissatisfied with elementary education, and with good cause. What they needed was skilled handicraftsmen.

On the morning of January 8 Mr. J. C. Medd opened the discussion on "Education Abroad and in England," and we hope to find space for an abridgment of his paper in another issue. Mr. Medd considers that the facilities for technical and scientific instruction are as great in England as in Germany, but the German has the advantage in the better quality of the pupils who attend those colleges and schools. In elementary education there is a great need for more practical instruction, some relaxation of the regulations as to building and equipment for manual instruction and domestic science, and the introduction of a system of supplementary courses.

Mr. Otto Siepmann attributed the high average excellence of elementary education in Germany partly to the thorough six-years' training which intending teachers receive in the training colleges, and partly to the fact that the field from which the teachers are drawn is not denuded of its most gifted scholars by any "educational ladder" which leads to other spheres of activity. In the secondary schools, also, individual prominence is sacrificed to raise the common average. All subjects are done in form, and practically the whole form is promoted from one stage to the next. Thus a particular aptitude for a special subject is never developed at school, but the German system ensures for every boy a sound general education. At the universities all this is changed, and the freedom which students are allowed in the choice of subjects, the general lack of supervision and of interim examinations, react favourably upon their work. They carry into life an active interest in some branch of knowledge, which they frequently pursue as long as they live.

Limitations of space prevent any reference to the discussions on art subjects and physical training, and allow merely brief reference to two other topics.

Miss Burstall admitted that the young people who now leave our secondary schools are to a large extent lacking in self-reliance and the power of independent work. She attributes this result to the pressure of the examination system, which forces the teacher, almost in self-defence, to do for the children half the work of gaining, arranging, and applying knowledge. Independent work by the scholars requires more time, which can be got only by reducing the number of subjects studied in any one year. The first thing to aim at, therefore, is to lighten the pressure of examinations.

Mr. W. B. Steer urged that much could be done to encourage independent habits of study by substituting silent reading, followed by keen questioning, for the ordinary reading lesson. At present excessive teaching leaves scant time for learning. Mr. E. E. Unwin spoke of the leisure-hour work and other forms of independent study practised in Bootham School, York.

On "The Relation of the State to the Training of Teachers of Domestic Subjects, and their Relation to the University," Prof. Smithells urged that the time had come for incorporating the training schools of cookery and other domestic subjects in an improved scheme for the general training of teachers, and for treating this important branch of work with less parsimony than hitherto. The domestic training schools should form an integral part of the women's training colleges, though not necessarily in the same building. At the same time, there was no reason except that of expense why a fuller curriculum of training in branches of knowledge relating to these subjects should not be provided in our modern universities, which already function as day training colleges for teachers seeking a more extended knowledge and the attendant degree in arts or science.

Miss M. Atkinson spoke of the introduction in London King's College for Women of two courses in domestic science, one for undergraduates and the other for post-graduate students. It was necessary in domestic economy to draw a sharp line somewhere between the minimum of hygienic knowledge and domestic skill, which should form a part of the education of everyone, and the specialised technique to be demanded of those who proposed to be experts in the subject; but in regard to the latter class especially, the basis of the training should be real and not sham science. The preliminary studies in physics, chemistry, physiology, and economics should consequently be provided by first-year courses at the university in these subjects, exactly as for students of engineering or medicine.

THE ETHNOLOGY OF CALIFORNIA.

THE University of California, continuing its useful work of investigating the ethnology and languages of the now rapidly disappearing Indian tribes of that State, publishes in the third part of the fifth volume of its Proceedings a monograph, by Mr. P. E. Goddard, on the Kato tribe, a branch of the Athapascan race on the Eel River. They have undoubtedly assimilated much of their culture from contact with the Pomos to the south and the Yukis to the east and west; but they still retain so much of their primitive folk-lore and beliefs that they deserve special examination. While their legends of the origin of fire and the sun are more or less common to other members of the group, their accounts of the creation and the deluge are peculiar to themselves. In the first, the earth with its great long horns raises itself from the primeval waters. The god Nagaitcho takes his seat upon it, places its head in the direction in which it should lie, and spreads clay between its eyes and upon each horn. Finally, in this he plants trees and other vegetables, and moulds the mountains and valleys.

In a second myth the gods Nagaitcho and Thunder cause the old, worn-out sky to fall, and replace it with a new firmament with four portals and four supporting columns, preparing at the same time summer and winter trails for the sun. Then follows a deluge, and the creation of fish and beasts of the sea. They then make man out of clay and woman out of one of his legs. In another myth Coyote steals the sun, which he finds tied up in a blanket in the house of an old woman. Out of pieces of the sun he creates the moon and stars. This series of myths, with other folk-tales, has been taken down from the lips of Bill Ray, who is apparently the last member of the tribe acquainted with the race traditions. Mr. Goddard has published the legends in the native language with an interlinear translation, and adds a free version which renders them intelligible. He admits that the record is fragmentary, and that they have probably lost some of their primitive form; but even with this qualification they will prove of interest to students of comparative mythology.

SOME APPLICATIONS OF MICROSCOPY TO MODERN SCIENCE AND PRACTICAL KNOWLEDGE.[1]

THE time is past when a man can expect to make any real contribution to knowledge by spreading his observations over the whole vast range of microscopic objects. In these days, in which the output of research on every subject is enormous, and is increasing rather than diminishing, a man is more likely to make progress and do useful work by taking up a special line and sticking to it. Speaking for those who work *with*, rather than *at*, the microscope, I would advise everyone who wishes his work to be fruitful in results to have a hobby of his own. In making this suggestion, I do not mean that we are all to become narrow specialists, interested in nothing but our own particular subject. Specialisation in work and in research does not necessarily mean specialisation in knowledge or in interests. The great value of such a club as ours is that by bringing together people occupied in different branches of work it enables one man to know what another man is achieving in a different line, thereby at once widening his outlook and stimulating him in his own work by producing a healthy spirit of emulation.

My advice, therefore, to the microscopist would be that he should aim at wide knowledge and diffuse interests, but should concentrate his activities and focus his attention on his own particular pet hobby, so that, by mastering a branch of natural knowledge, he may find himself in a position to advance it. However limited the field of study may be, however insignificant the objects may appear, yet something can always be found which, on the one hand, will illustrate some important and fundamental principle, or, on the other, will prove ultimately to have some direct or indirect bearing on human life and its needs. Let me give two instances in support of this statement. To the so-called practical man it may seem a very trivial occupation to worry about such things as Foraminifera, however beautiful their shells may be. Yet these tiny creatures, living in a sphere apparently so remote from our own, furnish wonderful illustrations of the powers and activities of primitive living matter, and Mr. Earland has recently directed our attention to the remarkable property they exhibit of selecting particular materials for building up their houses. This is a most interesting fact, well worthy of further study, especially by experimental methods, for it indicates that the most primitive and formless living matter possesses faculties of a kind which we term in higher forms of life instinct or intelligence. Again, a reputation for being an expert on, let us say, fleas, may provoke a smile from the uninstructed; but in view of the proved connection between fleas and human disease, especially plague, these paltry insects have now assumed very great importance as objects of study, and we find detailed descriptions of them in the reports of Government commissions. As Lord Crewe remarked in a recent speech, we commonly speak of any very trivial annoyance as a flea-bite; but we know now that in certain circumstances a flea-bite may cost a man his life. Small wonder, then, that fleas have become important objects of study to mankind.

This question of fleas and plague reminds me that I am here, not to preach a sermon, but to give an address, by recalling to my mind the subject which I propose to discuss to-night, namely, some of the remarkable advances that have been made during the last few years in our knowledge of human diseases caused by microscopic parasites. This is a subject which has now grown to such vast proportions that I must confine myself of necessity to a small part of it, namely, the diseases caused by Protozoa. As examples, I shall deal more especially with malaria, sleeping sickness, and yellow fever.

Malaria is a disease which was well known to the ancients, and is still very rife in many parts of Europe. It appears to have been prevalent formerly in the fen districts of England, but to have died out there from some unexplained reason. It is estimated by Prof. Ronald Ross to cause from a quarter to half the total disease in the tropics. It occurs under at least three forms, known commonly as tertian, quartan, and pernicious malaria, each of them easily distinguishable clinically, and due to distinct species of the parasite differing from one another in morphological characters, but similar in the general features of their life-cycle.

Until comparatively recent times nothing whatever was known of the nature of malaria or the manner in which it was acquired. It was generally believed that it was due to a poisonous miasma which arose from swamps and marshes, a notion conveyed in the name malaria—"bad air." This miasma theory is very prevalent in literature; for instance, in such a work as Dickens's "Martin Chuzzlewit," where the unfortunate settlers in Eden are supposed to contract fever by breathing the exhalations of the swamps.

The scientific study of malaria may be dated from 1880, when the parasite was discovered in the blood of fever patients by Laveran, then a military surgeon in Algiers. Laveran examined the blood microscopically, and observed the principal phases of the parasite. It was, however, some years before Laveran's parasite was accepted as the cause of malaria, though it ultimately obtained universal recognition. Even then it remained a mystery how the parasite got into the blood, and many still held to the miasma theory. It was supposed by some that the parasite passed out of the body and produced cysts or spores which could be disseminated by the wind, just as the cysts of many Infusoria are known to be carried by aërial currents, and that by inhaling these air-borne germs the disease was acquired. Others sought for the source of the infection in the contamination of drinking-water.

It remained for a countryman of ours to discover the true method of infection. Prof. Ronald Ross, then in the Indian Medical Service, experimented first with the very similar malarial parasites of birds, and found that the infection was taken from one bird to another by mosquitoes of the genus Culex. Similar experiments on human malaria gave at first negative results, until it was discovered that the necessary intermediate host of human malaria was a mosquito belonging to quite a different genus, Anopheles. These experiments were confirmed by many investigators in all parts of the world, and led to results which may be stated in two propositions, one positive, one negative, first premising that by a malarial infection is meant a new infection, not a relapse in a person previously infected.

(1) Malaria can be and is conveyed from sick to healthy persons by the agency of mosquitoes.

---

[1] From the presidential address delivered to the Quekett Microscopical Club on May 7, 1909, by Prof. E. A. Minchin, and published in the Journal of the Club for November, 1909.

(2) Malarial infection is not known to take place by any other method.

Experiments further showed, as I have mentioned already, the very remarkable fact that avian malaria can only be transmitted by culicine mosquitoes, and human malaria only by anopheline. If human blood containing the parasite be taken up by a Culex, the parasite cannot develop, but is digested up, along with the blood. The same thing happens to the parasite of avian malaria when taken up by an Anopheles.

Following on these experimental discoveries, the development of the parasite was studied microscopically in all countries by a great number of observers, amongst whom we may mention especially Grassi in Italy and Schaudinn in Germany. By their combined labours the complete life-history of the parasite has been worked out in the greatest detail, revealing one of the most fascinating chapters in natural history.

(An account was then given of the development of the malarial parasite, illustrated by a diagram.)

My second example, sleeping sickness, is also a disease that has been long known, though without attracting, until recently, so much attention as malaria. It was first observed in the West Indies in negro slaves imported from the west coast of Africa, the region in which it appears to be endemic. It was observed that the negroes suffering from it were not infectious, and that the disease did not spread to others—a fact easily explained by what is now known about the transmission of sleeping sickness, namely, that it is effected by flies of the genus Glossina, commonly known as tsetse-flies, which are confined at the present time to the African continent.

Of recent years this previously obscure disease has forced itself on the public attention by its having spread from its native haunts on the west of Africa and invaded regions previously free from its presence. In our protectorate of Uganda, in particular, it has caused terrible mortality, completely extirpating the natives in some parts, and numbering also many Europeans amongst its victims. I do not propose here to enter into the distressing symptoms of this deadly disease, but only to deal with what may be termed its natural history.

Before it is possible to understand clearly the nature of sleeping sickness it is necessary to say a few words about similar diseases in animals. It was well known to all African travellers from the time of Livingstone that domestic animals, especially cattle, horses, and dogs, were liable in Africa to a peculiar fatal disease known as nagana, caused by the bite of blood-sucking flies of the genus Glossina, the tsetse-flies, of which there are several species abundant in various parts of Africa. It was supposed that the fly produced and injected a virus which caused the disease.

The nature of nagana was first made clear by Sir David Bruce, who found that the cause of the disease was the presence in the blood of a minute flagellate or trypanosome, since named *Trypanosoma brucii*, and that the tsetse-fly did not generate the parasite, but was merely the unwitting agent in transmitting it from infected to healthy animals.

When the epidemic of sleeping sickness broke out in Uganda, the Royal Society, at the request of the Government, appointed a commission to investigate it, and Sir David Bruce was sent out as a member of the commission. A trypanosome was found by Castellani in the cerebro-spinal fluid of sleeping-sickness patients, and it was shown by Bruce and his assistants that this trypanosome was the cause of the disease, and that it was transmitted from sick to healthy persons by the bite of the local species of tsetse-fly, *Glossina palpalis*. It was proved by subsequent researches that the trypanosome causing sleeping sickness was identical with one that had been discovered previously in the blood of negroes in Gambia, and named *T. gambiense* by Dutton. In short, it was proved that sleeping sickness of man is a trypanosome disease similar to nagana of animals, but produced by a different species of trypanosome, transmitted by a different species of tsetse-fly, and running a somewhat different course. Whereas *Trypanosoma brucii* remains in the blood of its victims until their death, *T. gambiense* is found in the blood in the early stages of the disease, but spreads, probably through the lymphatic channels, into the cerebro-spinal fluid, and then causes the peculiar nervous symptoms which give the disease its name. The rapid spread of sleeping sickness into regions where it was previously unknown is an indirect consequence of the occupation of the African continent by European Powers. Formerly the native tribes were constantly at war with one another, and a negro never travelled any great distance from his own village. Now caravans move in every direction, and doubtless in this way the disease has been spread by porters and other natives already infected with the trypanosome coming into regions where tsetse-flies abound, and there infecting the flies, which in their turn have disseminated the infection amongst the previously healthy population.

Although it was proved experimentally that the disease is propagated by tsetse-flies, the exact method by which this is effected has remained hitherto somewhat mysterious. It was proved that the infection could be conveyed by what may be termed the direct mechanical method; that is to say, if a fly has sucked recently the blood of an infected person, its proboscis may contain living trypanosomes, and if it inserts its proboscis, immediately or a short time afterwards, into the skin of a healthy person, it may convey the infection simply by means of its contaminated proboscis. Experiments showed that infection in this direct manner only took place up to forty-eight hours after the fly had fed on the infected subject, and all attempts to obtain infection with flies at a longer interval than forty-eight hours gave negative results. Experimental evidence was therefore lacking for the existence of a developmental cycle of the parasite in the fly, although it was argued by many writers that for various reasons such a cycle must exist. Quite recently, however, a positive result has been obtained by Prof. Kleine, director of the German Sleeping Sickness Commission in German East Africa. Experimenting with nagana by feeding a batch of flies first on an infected animal and then on a long succession of healthy animals, he has made the most interesting and important discovery that the flies are not infectious at all until some three weeks after their first feed, and that then they infect every animal upon which they are fed. This result indicates that the incubation period—that is to say, the time occupied by the parasite in its cycle of development in the fly—is far longer than anyone had suspected, and that the negative results of former investigators are to be explained by their experiments not having been extended over a sufficiently long period. It must be borne in mind that to those working in tropical Africa it is often difficult, or even impossible, to obtain a sufficient number of experimental animals for such a protracted series of experiments.

From Prof. Kleine's experimental results it is evident that the trypanosome of nagana, and doubtless of sleeping sickness also, does undergo a cycle of development in the tsetse-fly, and the way is now open for the microscopist to rush in and to observe what becomes of the parasite in this long period that elapses between its being taken up by the fly and being given out again. We may expect that a fascinating and wonderful history will be made known of the transformations and migrations, the amours and the increase of the trypanosome in the bowels of the unconscious tsetse-fly; and we seem now to be in sight of a solution to the baffling problem of the transmission of diseases caused by trypanosomes.

The third disease I have chosen for my discourse, namely, yellow fever, is one sufficiently well known to everyone, by repute at least. There is no need for me to describe at length the dreaded "Yellow Jack," a malady often fatal, and always excruciatingly painful. The connection of this disease with mosquitoes has long been suspected, and has recently been proved conclusively by both the American and French commissions sent out to study the disease. The mosquito in this case is neither a Culex nor an Anopheles, but one belonging to a distinct genus, namely, *Stegomyia fasciata*, sometimes called the tiger-mosquito. It has been proved conclusively that the mosquito does transmit yellow fever, and it has also been proved that the disease is not communicated by direct infection or contagion through contaminated clothes or dwellings; and here let me direct attention to one great obstacle to conducting experiments on yellow fever—the fact, namely, that the disease is not communicable to animals, but only, so far as is known, to man. Hence experimental studies on the disease could only be performed on men who offered themselves voluntarily for this purpose. Such experiments were sometimes negative, sometimes positive, in their result; in the latter case, of course, the subject of the experiment acquired the disease, and in one case, at least, died of it. It would require the pen of a Shakespeare or a Milton to do adequate justice to such devotion on the part of these brave men to the cause of science and humanity.

By numerous carefully devised experiments a number of important facts relating to the transmission of yellow fever were elicited. It was shown that the unknown cause of the disease is in the blood of the patient only during the first three days of the illness, so that only during this period can mosquitoes become infected by sucking the blood of the patient. Consequently, if the patient be protected from mosquitoes for the first three days he ceases to be a danger to the community as a source from which the infection can spread. It was shown, further, that the mosquito, after acquiring the infection, goes through an incubation period of from twelve to fourteen days, during which it is not infectious; but after that it is infectious for the rest of its natural life; and a further point of interest was added by the French commission, namely, that an infected mosquito may transmit the infection to its offspring, so that a mosquito which has never fed on an infected person may be congenitally infectious.

I have chosen the instance of yellow fever to put before you because, although we have now such an accurate knowledge, gained by experiment, of the cause and transmission of the disease, no one has succeeded as yet in seeing the parasite itself. It is practically certain, for many reasons, that there is some minute parasite at work, and there are grounds for suspecting that the parasite is a spirochæte, one of those minute, actively flexible, thread-like organisms of which the affinities are so much in dispute at present, and which some authorities class with the Protozoa, others with the Bacteria; but here we have a case where the microscopist has been baffled, and where we get beyond the present limits of the powers of our instrument, a fact which should make us appreciate the labours of those who study the microscope and strive to perfect it.

Did time permit, I might mention many more important discoveries in the field of protozoan parasites causing disease. For example, there are the blood parasites of the genus Piroplasma (Babesia), causing fatal forms of hæmoglobinuria in various animals; they are not yet known for certain in man, but a species is known from monkeys, a source which is getting perilously near to us. Here the agent of infection is a tick of some sort, and usually the infection goes through two generations of ticks, being transmitted from the mother-tick, which has acquired the infection, to the numerous progeny of minute six-legged tick-larvæ, which in their turn infect the vertebrate host. Then there are the relapsing fevers caused by spirochætes in the blood, and said to be transmitted in Europe by bed-bugs, but in Africa by a species of tick which lives in mud floors. In India and other parts of the tropics we find that the deadly disease known as kala azar, due to a parasite, is transmitted in all probability by bed-bugs. All these and many others furnish points of great interest, but I must be content with the three examples with which I have dealt in more detail, in order to show you how great a work has been done and is being done in this field. As Prof. Osler said recently, these discoveries are going to have an enormous influence on the history of the world and of mankind, because they are going to make the tropics habitable by white men. We hear or read so often of such-and-such a country being uninhabitable by Europeans on account of its deadly climate; but when we look into the matter we find that it is not the climate at all that is to blame, but that the white races are killed off by diseases caused by some animal parasite with which they are inoculated by the bite of some bloodthirsty arthropod. Take Uganda, for instance, with which I have a slight acquaintance; all that the climate does for you there is to give you a sunstroke if you go out in the heat of the day with inadequate headgear, and to make it very difficult to keep awake after lunch. Some well-known European diseases, such as small-pox and syphilis, are also rife there; but, on the other hand, some of our familiar plagues, such as tuberculosis, rheumatic fever, and influenza, appear to be absent. The diseases that are really to be feared are all such as spring from bites of arthropods. If you protect yourself from the mosquito you will not get malaria; avoid the tsetse-fly, which is very easily done, and you are safe from sleeping sickness; do not sleep on mud floors, nor pitch your tent on old encampments, and relapsing fever will not trouble you; keep rats and fleas at a distance, and you are safe from plague. With a little care and attention to surroundings the European finds his life in the tropics, if anything, more free from disease than in our temperate but influenza-ridden Palæarctic climate.

In the foregoing remarks I have directed attention more particularly to the practical results of microscopy wedded to sagacious experiment, and have tried to show how fertile in good results this union has been, and promises still to be; but I would not have you go away with the impression that I advocate such studies solely on account of immediate practical good to be derived from them. Far from it. I am one of those who hold so-called theoretical and unpractical studies to be of the highest importance, and worthy of all support, if only for the reason that, being unremunerative, they often cannot support themselves. All history shows us that the knowledge of general principles must precede their application and practice, and that what is purely theoretical in one generation becomes thoroughly practical in the next or in a later one. There is no need for me to waste your time by multiplying instances of this familiar truth; but I will conclude with a few words on the wider applications of microscopy.

In the range of the natural sciences, two branches of knowledge stand at opposite poles, as judged from the standpoint of the objects with which they deal. The science of astronomy deals with the infinitely great; the science of biology, on the other hand, with the infinitely small. The astronomer with his telescope astounds us with the distant worlds he reveals to us; he thinks in millions of miles as ordinary persons deal with feet or yards; and he exhibits to us this world on which we live as but an insignificant planet, one of many, whirling round a star far inferior in magnitude to many of those we see nightly, a tiny speck in the vast ocean of space and matter, peopled by a race of puny creatures who style themselves the lords of creation, although their dominion does not extend over a billionth part of the universe. "The consciousness of an endless series of worlds," said Kant, "destroys my sense of importance, making me only one of the animal creatures which must return its substance again to the planet (that, too, being no more than a point in space) from whence it came, after having been in some unknown way endowed with life for a brief space."

Not less astounding, but in a totally different way, are the revelations of the biologist with his principal instrument of research, the microscope. With this he discovers continually new worlds invisible to the unassisted eye, and reveals infinite complexity in things apparently the most simple. We find, in the first place, our own bodies to be microcosms, small worlds, that is, of such inexhaustible variety and elaboration of detail that to the human mind they are as difficult to comprehend and to realise in their entirety as the macrocosm or great universe itself. We find, further, that each human body, itself appearing as a single individual or unit, is in reality made up of many billions of living units or cells, each as much a microcosm as the whole body; and thus our instrument, the microscope, brings us face to face with the greatest mystery in the whole range of the sciences, namely, the problem of life and living matter. There is, apparently, no gap in nature so profound as that which separates the living from the not-living. The nature of life, its origin and destiny, the laws that govern living matter and vital processes of all kinds, these are of all problems not merely the most fundamental in science and philosophy, but also the most important for our practical knowledge and daily conduct.

It would be futile to assert that human science has as yet made any great advance in elucidating the nature of life. On the contrary, all progress in research only throws into greater relief the difficulty of the problem; the better we become acquainted with it, the more the mystery deepens. Nor would it be right to assert that the microscope is the sole instrument of research in this field. Our knowledge of the properties and activities of the living substance and of living things advances daily by leaps and bounds through methods of investigation in which the microscope plays no part. I have referred to the knowledge that has been gained of the life-history of the parasite of yellow fever, in spite of the fact that the microscope has failed completely, so far, to detect the parasite itself. But we may safely claim that the greater and most important part of modern biological knowledge could not have been gained without the instrument which it is the object and purpose of our club to study, to perfect, and to apply; and, further, that to be able to see the objects with our own eyes makes them much more real and true to us than merely to infer their presence and properties from experiments in the dark, so to speak. "Seeing is believing" is an English proverb which has its counterpart in all languages. We may be satisfied in our minds as to the existence and behaviour of the yellow-fever parasite, but nevertheless its discovery by optical means would be greatly welcomed as an important advance in our knowledge.

There is no greater stimulant to the all-important study of living things than the feeling of wonder and delight which the first sight under the microscope of objects otherwise invisible produces in even the most uninstructed mind. Most of us probably can date our first interest in minute living objects from the time when, perhaps in early youth, we were given, or allowed to use, a microscope, with which we could gratify, without satisfying, our curiosity in looking at all kinds of minute objects. In such an occupation the appetite comes with eating, as the French proverb says, and the instrument which was at first a fascinating toy leads us on until, one might almost say, it masters and enslaves us. In this development there is another instance of the parallel between the progress of the individual and the history of the race. To the majority of early microscopists the microscope was but a toy, an instrument which competed with the magic-lantern as an amusement for drawing-room séances, and only a serious minority made use of it as a means of earnest scientific investigation. There are, perhaps, still microscopists whose chief delight is to thrill their friends, especially those of the fair sex, by the sight of hairs on a spider's leg, or the elephantine proportions of a cheese-mite. If so, let us not scoff, as some do, at the amateur; we ought rather to regard him with the same interest that a zoologist looks on an okapi or a lepidosiren, as a living representative of a bygone age. For the modern microscopist is fearfully in earnest, and has but little opportunity for amusement in pursuing a science which taxes, not only his brain, but his eyes to the utmost. There is scarcely any greater physical strain than the long-continued investigation carried on with the highest powers of the microscope, and in my own experience I have known some who lacked the physical endowment for such work, and others who have been obliged to retire disabled from the field. Let us, then, in a pursuit which but too frequently dulls enthusiasm by fatigue and exhaustion, in which our "native hue of resolution" tends to become "sicklied o'er by the pale cast of thought," rather envy those who retain the freshness of their early delight, and strive to cultivate, rather than to stifle, that feeling of wonder and curiosity which should be the starting point of all philosophical and scientific investigation. "Two things," said Kant, "fill my mind with ever-renewed wonder and awe, the more often and the deeper I dwell on them—the starry vault above me and the moral law within me." I venture to think that had Kant lived in our days he would have found a third source of wonder in the contemplation of the simplest living things as revealed by the microscope, in the combination they present of apparent simplicity with infinite complexity, and of extreme minuteness with the most extraordinary powers. To me the observation of a minute organism, such as an amœba, under the microscope, is in its way as marvellous as the sight of the starry firmament. I see a minute, formless creature, without definite parts or organs, which nevertheless exercises all the functions of life and exhibits the germ of every faculty we possess, and thereby proves that its apparent simplicity and formlessness cloak a complexity of organisation far transcending our powers of observation and eluding our means of detection. What, again, can be more wonderful to contemplate than the fact that peculiarities in the complex mental endowment and physical structure of a human being can be transmitted from one generation to the next through the medium of a spermatozoon, the tiniest cell of the human body, in which the microscope reveals only a structure of the simplest kind? These things must rank with the most wonderful and inexplicable of the phenomena that nature presents to us, and we are as yet only on the threshold of investigation. The stellar universe has been observed, its laws and motions studied, for many thousands of years, but our acquaintance with the beginnings of life and its properties as exhibited by the simplest living things is but an affair of yesterday, as it were, and the scientific study of life is as yet in its infancy.

In these days of vast and rapid increase of knowledge in such matters there is danger that we may lose the true perspective, and that our perception of the whole may be blunted and obscured by the immense mass of detail which forces us to attend only to a small part of our science. It is the special function of a club such as ours to keep fresh our enthusiasm and to enlarge our outlook by contact and intercourse with those working in other fields, to spread the infection, if I may use the term, of intelligent curiosity in the minutest natural objects, and thereby to attract and enlist new workers in a field in which the harvest is plentiful but the labourers are few.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The electors to the Allen scholarship give notice that they are prepared to receive applications from candidates. Any graduate of the University is eligible for the scholarship provided that his age on the first day of the Lent term, 1910, does not exceed twenty-eight years. This year the scholarship is open to candidates who propose to undertake research in any branch of study which comes within the department of any of the following special boards:—medicine, mathematics, physics and chemistry, biology and geology. The scholarship is tenable for one year, during which period it will be the duty of the student to devote himself to research in Cambridge or elsewhere. The emolument of the student is 250*l*., or such smaller sum as the fund, after payment of all expenses, shall be capable of providing. Every candidate must send to the Vice-Chancellor, Pembroke College Lodge, on or before February 15, his name and a definite statement of the course of research which he proposes to undertake, together with such evidence of his qualifications as he thinks proper, and with the names of not more than three referees to whom the electors may apply for information.

THE University of California has received from Mrs. Phœbe Hearst an offer to build, at the cost of about 100,000*l*., a museum for the housing of its anthropological specimens. During the last ten years Mrs. Hearst had already contributed an equal sum to the establishment and maintenance of the University's department of anthropology, and to the cost of its foreign expeditions.

ACCORDING to the Berlin correspondent of the *Times*, the latest returns from the German universities give the total number of students as 52,407, including 1850 women, as compared with a total of 48,730 last year and 32,800 ten years ago. There are also 3314 men and 1923 women attending courses as guests. Berlin takes the first place among the twenty-one universities with 9242 students, as against 8641 last year, and is followed by Munich with 6537, Leipzig with 4761, Bonn with 3652, Breslau with 2405, and Halle with 2393. Göttingen has 2230, and Heidelberg 1934. In Berlin University this winter there are 632 women students, an increase of 232 as compared with last year.

AN address delivered by Prof. Alexander Smith before the section of education of the American Chemical Society at Detroit, and reproduced in a recent number of *Science* under the title "The Rehabilitation of the American College and the Place of Chemistry in It," is of more than local interest and importance. The author is strongly impressed with the difficulty of teaching his subject effectively to classes of students of widely varying mental capacities, and especially of teaching it in such a way as to be of service to those who do not expect to become professional chemists. He is a profound disbeliever in the method of imparting instruction which relies mainly upon lectures, and urges that the essential feature of all teaching should be "problem-solving" in some form or other. This method, he suggests, is fully developed in the teaching of languages, in which "the grammar furnishes the laws and general principles, together with all the known exceptions," "the dictionary supplies the isolated facts," and "the text provides the subject of study in constant and definite form." In the case of chemistry, he urges a closely interwoven scheme of laboratory work and class-room discussion, supplemented (if lectures are used) by briefly written answers to set questions and home study in varying amounts to suit the necessities of the individual student.

THE annual general meeting of the Association of Headmasters was held in London on January 12 and 13. Mr. Philip Wood, headmaster of Darlington Grammar School, the president for the year, in his presidential address referred to the question of the provision of free places in secondary schools receiving grants from the Board of Education. He said there are many grammar schools in towns with a population of less than 20,000 which educate the sons of the professional people and better-class tradesmen, but depend largely for their existence on being able to attract boarders. The position of such a school at the present time is very precarious. It has had always something of a struggle, and the grants of local education authorities and of the Board of Education are just what it requires to give it new life; but the grants are conditioned, and the conditions, at least of the Board of Education, would seem to contemplate a large day school in a large town rather than the kind of school in question. In a small market town, for instance, it is ridiculous that a school of, perhaps, seventy-five boys should be increased to 100 in order to provide for the education of twenty-five boys from the two or three elementary schools in the town. Boys capable of taking advantage of these opportunities are not to be found; and what is also a matter of common experience, their admission, whether they are capable or incapable, generally means the displacement of an equal number of boys whose parents do not like the new situation. Thus the 25 per cent. rule, which does not greatly embarrass a large day school, will, if rigorously applied, almost ruin many schools which we can ill afford to lose.

THE Department of Agriculture and Technical Instruction for Ireland has issued a pamphlet giving an account, by Mr. George Fletcher, assistant secretary for technical instruction, of the summer courses of instruction for teachers instituted by the Department in 1901. The courses are held in July and August, and extend over a period of about a month. They are held in Dublin and elsewhere. In selecting teachers to attend the courses, regard is had to the qualifications of the teachers and the needs of the school or district from which they come. After each year's course, teachers who pass the examinations are provisionally recognised as qualified to teach the subjects in which they have passed. Courses are held in experimental science, drawing, manual work in wood, and domestic economy. Besides preparing teachers to conduct classes in the Department's "Programme for Day Secondary Schools," the summer courses are year by year coming to serve a further purpose. Side by side with the development of the Department's scheme in day secondary schools there has grown up a system of specialised technical education all over Ireland. The rate of growth has been rapid, and a large and increasing number of Irish teachers are engaged in the schools and classes organised through urban and county councils. While it was necessary in the initial stages of such a system to employ teachers having experience of similar work, from whatever source they might be obtained, special efforts have since been made to train Irishmen when and where possible. Hence it is that year by year an increasing number of summer courses are organised to deal with subjects purely technical in character and having for their object the further education and training of teachers already engaged in Irish technical schools. It would be difficult to over-estimate the value of these courses as an element of educational progress. The typical courses described in the pamphlet by means of syllabuses, descriptions, and illustrations indicate what great pains have been taken by the authorities to make the lectures and practical work meet the needs of the teachers exactly.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 13.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir Edward **Thorpe** and A. G. **Francis**: The atomic weight of strontium.—L. F. **Richardson**: The approximate arithmetical solution by finite differences of physical problems involving differential equations, with an application to the stresses in a masonry dam. In order to deal with irregular boundaries, analysis is replaced by arithmetic, continuous functions are represented by tables of numbers, differentials by central differences. Then problems fall into two classes. (A) The relation between the equation obtaining throughout the body and the boundary condition is such that the integral can be stepped out from a boundary. This class includes equations of all orders and degrees. It has been treated by arithmetical differences by Runge, W. F. Sheppard, Karl Heun, W. Kutta, and Richard Ganz. Examples of a specially simple method are given. (B) The integral must be determined with reference to the boundary as a whole, as in Dirichlet's problem. The method given has only been worked out for a limited group of linear equations, namely, for those in connection with which a function analogous to potential energy exists, which is a complete minimum when and only when the difference equations are satisfied. Under this condition the difference between the integral ϕ_u and a function ϕ_1 of the independents, having the correct boundary conditions but otherwise arbitrary, can be expanded in the form $\phi_1 - \phi_u = \Sigma A_k P_k$ where the A_1s . . . A_n are constants and P_1 . . . P_n are "principal modes of oscillation" defined by $\mathbf{D}'P_k = \lambda_k{}^2 P_k$ where $\mathbf{D}'\phi_u = 0$ is the difference equation to be integrated and λ^2 is a constant. Now we start with the table of numbers ϕ_1 and calculate $\mathbf{D}'\phi_1$. Then as $\mathbf{D}'\phi_u = 0$ we have $\mathbf{D}'\phi_1 = \mathbf{D}'(\phi_1 - \phi_u) = \Sigma A_k \lambda_k{}^2 P_k$. Multiplying both sides by some number $\alpha_1{}^{-1}$ and subtracting from ϕ_1, and altering the boundary numbers so that the boundary condition is still satisfied, we have a new table which may be called ϕ_2; and $\phi_2 - \phi_u = \Sigma A_k(1 - \alpha_1{}^{-1}\lambda_k{}^2)P_k$. Repeating the process with $\alpha_2 \ldots \alpha_m$ we get:

$$\phi_{m+1} - \phi_u = \Sigma A_k(1 - \alpha_2{}^{-1}\lambda_k{}^2)(1 - \alpha_2{}^{-1}\lambda_k{}^2) \ldots (1 - \alpha_m{}^{-1}\lambda_k{}^2)P_k.$$

Now a function I exists such that $\mathbf{S}IP_k{}^2 = 1$, $\mathbf{S}IP_l P_k = 0$ where **S** denotes a summation throughout the region. Therefore:

$$\mathbf{S}I(\phi_{m+1} - \phi_u)^2 = \Sigma[A_k(1 - \alpha_1{}^{-1}\lambda_k{}^2) \ldots (1 - \alpha_m{}^{-1}\lambda_k{}^2)]^2.$$

Now by a sufficient number of suitably chosen αs the polynomial in λ^2 on the right can be made small throughout the range from $\lambda_1{}^2$ to $\lambda_n{}^2$. Therefore the error of ϕ_{m+1} can be made small; for, since I is one signed it is measured by the L.H.S. The process is arithmetical. The error due to finite central differences is of the form

$$e_2 h^2 + e_4 h^4 + e_6 h^6 + \text{ \&c.},$$

where h is the coordinate difference and the *es* are functions of position independent of h. If the integral has been found for two or more sizes of h, more exact values of it can be extrapolated by this formula. These methods have been applied in the paper to calculate the stress-function in a masonry dam.—A. O. **Rankine**: A method of determining the viscosity of gases, especially those available only in small quantities.—Dr. P. **Phillips**: Recombination of ions at different temperatures.—Dr. G. C. **Simpson**: The electricity of rain and snow. This paper relates to measurements of the electricity of rain made in continuation of those described at the beginning of last year (Phil. Trans., Series A, vol. ccix., pp. 379–413, 1909), and, in addition, to a series of measurements of the electricity of snow made during the winter 1908–9. All the main conclusions drawn from the previous work have been confirmed, and it may now be stated with confidence that in Simla (*a*) more than three times as much positive as negative electricity is brought down by the rain; (*b*) the heavier the rainfall, the more likely is it to be positively charged; (*c*) light rain is, as a rule, more highly charged than heavy rain, irrespective of whether the charge is positive or negative. With regard to the electrification of snow, the measurements indicate that in Simla (*d*) the positive charge carried down by the snow is between three and four times as great as the negative charge; (*e*) snow is generally more highly charged than rain.—L. **Vegard**: The polarisation of X-rays compared with their power of exciting high-velocity kathode rays.

Mathematical Society, January 13.—Sir W. D. Niven, president, in the chair.—Dr. H. F. **Baker**: (1) The theory of the cubic surface; (2) an example of the expansion of a function in a series of polynomials.—G. N. **Watson**: The harmonic functions associated with the parabolic cylinder.—Dr. H. de S. **Pittard**: Note on the theory of sets in probabilities.—H. **Bateman**: The transformations of coordinates which can be used to transform one physical problem into another.—G. H. **Hardy**: Note on a former paper on the theory of divergent series.—Dr. W. H. **Young**: Homogeneous oscillation of successions of functions.—Dr. W. H. **Young** and Mrs. G. C. **Young**: The determination of a semi-continuous function from a countable set of values.—J. E. **Campbell**: Cyclic congruences.

Royal Astronomical Society, January 14.—Sir David Gill, K.C.B., president, in the chair.—J. **Evershed**: Radial movement in sun-spots: second paper. The paper contained further investigations on the spectra of sun-spots, made at the Kodaikánal Observatory, India. The spectra of every considerable spot had been photographed, and it was invariably found that, except when the spot was near the centre of the disc, the lines crossing the spot were inclined towards the red on the side nearest the limb, and towards the violet on the side nearest the centre of the disc. Assuming this inclination to be due to motion in the line of sight, the conclusion seemed inevitable that spots are centres of a force directed outwards in a horizontal plane. This would explain the motion of recession on the side nearest the limb, and of approach on the side nearest the centre of the disc. The effect would not be observed in the case of a spot near the central meridian, where there would be no motion in the line of sight. A study of the calcium lines showed a motion in the opposite direction (towards the centre of the spot), indicating an in-draught of calcium vapour in the higher chromosphere. No evidence was obtained of an upward current over spots, but there were some indications of downward movements. There are also indications of cyclonic motion, but in the opposite direction to that shown in some of Prof. Hale's spectroheliographs.—A. C. D. **Crommelin**: Diagram illustrating a method of charting the geocentric places of a comet referred to a fixed radius vector.—R. W. **Wood**: The moon in ultra-violet light; spectro-selenography. The author recommended a spectroscopic method of investigating the nature of the surface of the moon.

Institute of Metals, January 18.—Sir William H. White, K.C.B., F.R.S., president, in the chair.—G. D. **Bengough** and B. P. **Hill**: The properties and constitution of copper-arsenic alloys. One of the principal objects of the paper was to bring forward data for an authoritative pronouncement upon the best proportion of arsenic to be used to secure copper alloys having greater strength and rigidity, and greater resistance to the corrosive action of gases at high temperatures, than commercially pure copper. The first portion of the paper dealt with the mechanical properties of the alloys of industrial importance, and the second with their chemical composition. In the latter section the authors denied the existence of the compound Cu^2As, proposed by Hiorns, and confirmed the existence of the compounds Cu_3As and Cu_5As_2, already proposed by Friedrich.—E. A. **Smith**: The assay of industrial gold alloys. The author gave a brief comparative description of the methods in general use for the assay of industrial gold alloys, based on experimental work carried out at the Royal School of Mines and in the University of Sheffield. It was shown that the results for gold assay were invariably higher when determined by direct cupellation with parting silver than when determined indirectly by double cupellation.—Dr. R. **Seligman** and F. J. **Willott**: The analysis of aluminium and its alloys. A detailed description was given of the technical methods of estimating the various foreign elements (copper, zinc, nickel, magnesium, tin, lead, manganese, titanium) and impurities (silicon, iron, and sodium) to be found in commercial aluminium and aluminium alloys. It was pointed out that the effect of these elements, particularly in minute proportions, upon aluminium was but little understood, and that it was desirable that research be directed along those lines.

EDINBURGH.

Royal Society, December 20, 1909.—Sir William Turner, K.C.B., president, in the chair.—Sir William **Turner**: The aborigines of Tasmania, part ii., the skeleton. The paper gave further particulars as to the specimens of Tasmanian skulls and skeletons now extant, and described in detail the bone anatomy of the specimen in the museum at Brussels. The discussion emphasised the fact that the Tasmanian had differed in important particulars from the ordinary black races, but resembled them in other respects. As regards the flattened femurs, the Tasmanian suggested affinity with the cave-dwellers and the Maoris, whereas in the form of the pelvis there was greater resemblance to the European races.—W. T. **Gordon**: The structure and affinities of *Zygopteris Römeri* (Solms). The petiole of this form was described by Solms Laubach from the Culm of Falkenberg. A few years later a similar petiole was obtained by Renault from rocks in Autun, and called *Diplolabis Esnostensis*. The present specimens of stems, petioles, and roots were found last year by the author in rocks of Calciferous Sandstone age at Pettycur, in Fife. The stem is protostelic, and is circular in transverse section. The wood consists of an inner zone with short elements, and an outer zone with longer tracheides. All the wood elements, whether long or short, have reticulate thickenings in their walls. The stem branches dichotomously. Appendages are given off from the stem at long intervals. These are either petioles or roots. At successive levels in the petiole the trace is indistinguishable from the characteristic trace in several different genera. *Zygopteris Römeri* is thus a synthetic type so far as the stages in the development of its petiole are concerned, and in the possession of a protostele the plant is the most primitive zygopterid yet discovered. In its organisation it has an important bearing on the origin of the Botryopteridæ and the Osmundaceæ.—Prof. Gwynne **Vaughan** and Dr. R. **Kidston**, F.R.S.: The fossil Osmundaceæ, part iv., and conclusion. Two new species are described, *Osmundite Kolbei* and *O. Schemniciensis*. The latter is closely similar to the modern Osmunda, but the anatomy of the former is described for the first time. It is very interesting owing to the position it takes up between the Osmundaceæ that have a solid xylemed stele and those with a broken ring of xylem surrounding a pith. The xylem is broken up into separate strands, but its pith contains scattered groups of tracheal elements. The general results of the whole paper are summed up, and the relationships between the Osmundaceæ and the Zygopterideæ are discussed in some detail, especially with reference to the peculiarities of the structure of the zygopterid leaf-trace.—Prof. J. C. **Ewart**, F.R.S.: The restoration of an ancient race of horse. About the middle of last century Owen received two upper molar teeth of a small member of the Equidæ family from a cavernous fissure at Oreston, near Plymouth. Similar teeth were obtained from the drift lying over the London at Chatham and from Kesingland, in Suffolk. Owen realised that these molars could not belong to a small variety of *Equus fossilis*—the species now represented by the wild horse (*E. przewalskii*) of Mongolia—but he had some difficulty in deciding whether they were the teeth of a small race of horses or the teeth of an ass or a zebra. Eventually he concluded that the Oreston teeth belonged to a "wild ass or quagga," which, with a wild horse and a wild boar, entered "into the series of British Pliocene hoofed mammals." To this fossil wild ass or zebra Owen gave the name of *Asinus fossilis*. In addition to the last two upper molars there is preserved in the British Museum a first upper molar from Oreston which probably belonged to an animal between ten and eleven hands at the withers. In this small first molar the grinding surface of the "internal pillar"—a fold of enamel on the inner surface of the tooth—is only one-third the length of the grinding surface of the crown. In having a small internal pillar or protocone in this first upper molar, the Oreston type differs profoundly from the wild horse of Mongolia, but resembles (1) the small horses which at the beginning of the Pliocene period lived in Nebraska, *i.e.* horses of the Pliohippus group; (2) a small race which towards the close of the Pliocene frequented the valley of the Arno—a race hitherto included in the *E. stenosis* group; (3) a small variety which in Pliocene times lived in Auvergne and other parts of France, sometimes known as *E. ligeris*; and (4) a small equine which in Pleistocene times occurred in Algiers, to which M. Thomas gave the name *E. asinus atlanticus*. M. Boule regarded the last two as closely related, and as probably the direct ancestors of the zebras now living in South Africa. The Italian, French, and English deposits have also yielded cannon bones—metacarpals and metatarsals—as slender as those of the fine-boned desert Arabs, but not so slender as the cannon bones of the Onager and other wild asses of Asia. From inquiries extending over some years, Prof. Ewart had ascertained that there were small horses in the Roman Fort at Newstead, near Melrose, with molars of the same type as those from Oreston, and with cannon bones as slender as the fossil ones from the Valley of the Arno, Auvergne, and Kent's Cave, Torquay. Further, in a six-year-old Shetland pony of the Celtic type he had recently noticed that the first upper molars, in size as well as in the enamel foldings, were practically identical with the small first Oreston molar in the British Museum. He was of the opinion that the teeth said by Owen to belong to a fossil ass or zebra really belonged to a small race of horse, from which have in part descended the modern Exmoor, Welsh, Shetland, and other ponies of the Celtic type. To this small, true horse, which in Pleistocene times probably ranged from Algiers to the south of England, he had given the name *Equus agilis*—the more appropriate name *gracilis* not being available. Bearing in mind that several of the zebra hybrids which he had bred some years ago seemed, at least in their markings, to reproduce ancestral types, he decided to try to restore the small race which lived in the south of England along with the mammoth. By blending all the available Occidental and Oriental breeds, Prof. Ewart had now obtained several ponies which probably in make, disposition, and colour, as well as in limbs and teeth, fairly accurately reproduced the small, slender-limbed species hunted and sketched or sculptured by our Palæolithic ancestors. The pony which probably restores most accurately the small, fine-boned prehistoric race has a fine head, slender limbs and small hoofs, a mane which instead of clinging to the neck arches to one side, a well set-on tail, and only two of the eight callosities usually found in horses, *i.e.* the four ergots and the hind chestnuts are absent. This pony, like the other forty crosses bred, cannot be described as "more or less striped"—there is only a narrow dorsal band and a faint shoulder stripe—and hence lends no support to the view that in prehistoric times all the wild horses were at least as richly decorated as the recently extinguished quagga, or to M. Boule's view that the small horse which in Pleistocene times inhabited the south of France and North Africa is the direct ancestor of the zebras now living in South Africa. Though this hybrid pony is, like the wild horse of Mongolia, of a yellow dun colour, and is a mixture of seven more or less well-marked breeds, namely, Connemara, Welsh, Hackney, Iceland, Hebridean, Shetland, and Arab, it excels in make, action, and intelligence all the other ponies of a like age—an indication perhaps that, notwithstanding its mixed origin, it possesses the traits of an ancient wild race.

PARIS.

Academy of Sciences, January 10.—M. Émile Picard in the chair.—H. **Deslandres**: The magnetic storm of September 25, 1909, and the connected solar phenomena. A verification of some theories proposed. A discussion of the various theories of the influence of the sun on the earth. The author regards the theory of kathode radiation put forward by himself and by Birkeland as offering a sufficient explanation of the observed facts. It explains the delay of forty-five hours of the magnetic storm with respect to the passage of the active spot across the central meridian, and is connected with the author's theory of nebulæ.—J. **Carpentier**: Remarks on a frequency meter constructed from the designs of Commandant Ferrié, and also on a small precision balance constructed by M. Collot. The weights, from 50 grams to a decigram, are introduced on the pans by pressing buttons external to the balance case; the smaller weights are read by a microscope as deviations of the pointer. The balance works at constant load—100 grams—and by substitution, and is very rapid in its indications.—C. **Guichard**: The surfaces of total constant curvature which correspond to singular systems of any order.—C. **Russyan**: The theorem of W. Stekloff (the generalised theorem of Jacobi) and generalised formulæ of contact transformation.—Henri **Lebesgue**: The integral of Stieltjes and linear functional operations.—J. **Le Roux**: Definite quadratic forms with an infinity of variables.—E. **Jouguet**: The impossibility of certain waves of shock and combustion.—E. **Estanave**: Images changing from two or three points of view on the autostereoscopic plate.—Edm. **van Aubel**: The production of ozone under the influence of ultra-violet light. The production of ozone by the action of ultra-violet light, first observed by Lenard, has been confirmed by other observers. On the other hand, H. Bordier and T. Nogier have recently described experiments leading to the contrary conclusion. The experiments detailed in the present paper confirm Lenard's experiments.—F. **Ducelliez**: The study of some alloys of cobalt from the point of view of their electromotive forces. Curves are given for the experimental measurements with alloys of cobalt with tin, antimony, bismuth, lead, and copper.—A. **Besson** and L. **Fournier**: A new chloride of phosphorus. No chloride of phosphorus corresponding to the hydride P_2H_4 and the iodide P_2I_4 has hitherto been described. This chloride, P_2Cl_4, is produced by the action of the silent electric discharge on a mixture of hydrogen with the vapour of phosphorus trichloride. The new chloride forms a colourless, oily liquid, solidifying at $-28°$ C., and distilling with slight decomposition at 95° C. under a pressure of 20 mm. It absorbs oxygen rapidly from the air, and sometimes catches fire spontaneously. Attempts to isolate the corresponding bromide were unsuccessful.—Marcel **Delépine**: The solution of platinum in sulphuric acid, and on the products of this reaction. The presence of oxygen is not necessary to the reaction between platinum and sulphuric acid, as has been assumed by M. Quennessen, since solution takes place in a stream of carbon dioxide, air, oxygen, or carbon dioxide mixed with sulphur dioxide.—Pierre **Jolibois**: Two new phosphides of nickel. These compounds were obtained by heating a nickel-tin alloy in sealed tubes with phosphorus. The composition of the phosphides agreed with the formulæ NiP_2 and NiP_3.—E. **Cornec**: The formula of hypophosphoric acid. A cryoscopic study of aqueous solutions of the acid and the potassium salt. The double formula $H_4P_2O_6$ agrees best with the facts observed.—J. B. **Senderens**: The catalytic preparation of the aromatic ketones. The catalytic action of thoria at 460° C. upon a mixture of benzoic and a fatty acid gives a mixture of the symmetrical fatty ketone and the mixed fatty aromatic ketone, no benzophenone, apparently, being formed. The method has been successfully applied to the preparation of ketones of the general formula C_6H_5—CO—R, in which R was methyl, ethyl, normal and isopropyl, and isobutyl.—M. **Lespieau**: Methylacetenylcarbinol.—Em. **Bourquelot** and M. **Bridel**: The presence of gentiopicrin in *Chlora perfoliata*. Details are given of the methods employed for isolating this glucoside in the pure state.—H. **Bierry**: Researches on the digestion of inulin. It is found that various animals are capable of digesting inulin, but they employ for this digestion different physiological agents. In the higher animals, the transformation of the inulin takes place in the stomach, and is due to the hydrochloric acid of the gastric juice; in molluscs a ferment is secreted which is capable of hydrolysing the inulin to levulose.—J. **Sarthou**: The presence in cow's milk of a catalase and an anæroxydase. The statement of MM. Bordas and Touplain that the insoluble casein of milk is capable of decomposing hydrogen peroxide is denied, and experiments detailed which tend to show that this action is due to a mixture of a physiological catalase and a bacterial catalase.—Louis **Roule**: The structure of the epidermal protuberances of certain Amphibia and their morphological affinities with the nails. —J. **Nageotte**: A new formation of the myeline layer.—J. **Mawas**: The structure of the ganglion nerve cells of the amyelinic cord of the Cyclostomes.—A. **Contamin**: The immunisation against cancer of mice inoculated with tumours modified by the X-rays.—L. **Bull**: The mechanics of insect flight.—C. **Levaditi** and K. **Landsteiner**: Researches on experimental infantile paralysis. The preventive inoculation of animals by means of the dried spinal cord is possible.—A. **Thiroux** and W. **Dufougeré**: A new spirilla from *Cercopithecus patas*. This organism resembles in its morphological characters the *Spirillum duttoni* of tick fever, from which, however, it is distinct. The name *Spirillum pitheci* is proposed.—L. **Cayeux**: The prolongation of the Silurian oolitic iron deposits under the Paris basin.—E. **de Martonne**: The mechanical theory of glacial erosion.—Alfred **Angot**: The value of the magnetic elements at the Val-Joyeux Observatory on January 1, 1910.—E. **Esclangon**: The intensity of gravity and its anomalies at Bordeaux and neighbourhood.—E. **Péroux**: The mineral contents and chemical analysis of the water from the artesian wells of Maisons-Laffitte.—André **Brochet**: New determinations of the radio-activity of the thermal springs of Plombières. These springs are strongly radio-active, this effect being due to the radium emanation.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 20.

ROYAL SOCIETY, at 4.30.—Further Observations on the Pathology of Gastric Ulcer (Progress Report): Dr. C. Bolton.—(1) The Velocity of Reaction in the "Absorption" of Specific Agglutinins by Bacteria, and in the "Adsorption" of Agglutinins, Trypsins, and Sulphuric Acid by Animal Charcoal; (2) On the Absorption of Agglutinin by Bacteria, and the Application of Physico-chemical Laws thereto: Dr. Georges Dreyer and J. Sholto Douglas.—Observations on the Rate of Action of Drugs (Alcohol, Chloroform, Quinine, Aconitine) upon Muscle as a Function of Temperature: Dr. V. H. Veley, F.R.S., and Dr. A. D. Waller, F.R.S.—An Examination of the Physical and Physiological Properties of Tetrachlorethane and Trichlorethylene: Dr. V. H. Veley, F.R.S.—The Action of Antimony Compounds in Trypanosomiasis in Rats: J. D. Thomson and Prof. A. R. Cushny, F.R.S.—"Amakebe" (a Disease of Calves in Uganda): Colonel Sir David Bruce, F.R.S., Captains A. E. Hamerton and H. R. Bateman, R.A.M.C., and Capt. F. P. Mackie, I.M.S.—On Scandium: Sir William Crookes, For.Sec.R.S.

ROYAL INSTITUTION, at 3.—Assyriology: Rev. C. H. W. Johns.

LINNEAN SOCIETY, at 8.—Discussion on the Origin of Vertebrates: Dr. Gaskell, Dr. Gadow, Mr. Goodrich, Prof. Starling, Prof. MacBride, Dr. Smith Woodward, Prof. Dendy.

INSTITUTION OF MINING AND METALLURGY, at 8.—Copper Leaching Plant in the Ural Mountains: A. L. Simon (*Adjourned discussion.*)—Some Analyses of Copper Blast Furnace Slags and Determination of their Melting Points: A. T. French.—The Detection of Minute Traces of Gold in Country Rock: A. R. Andrew.—Errors due to the Presence of Potassium Iodide in testing Cyanide Solutions for Protective Alkalinity: B. Collingridge.

FRIDAY, JANUARY 21.

ROYAL INSTITUTION, at 9.—Light Reactions at Low Temperatures: Sir James Dewar, F.R.S.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Ninth Report to the Alloys Research Committee: On the Properties of some Alloys of Copper, Aluminium, and Manganese (with an Appendix on the Corrosion of Alloys of Copper and Aluminium when exposed to the Sea): Dr. W. Rosenhain and F. C. A. H. Lantsberry.

PHYSICAL SOCIETY, at 5.—Saturation Specific Heats, &c., with van der Waals' and Clausius' Characteristics: R. E. Baynes.—The Polarisation of Dielectrics in a Steady Field of Force: Prof. W. M. Thornton.—On the Use of Mutual Inductometers: Albert Campbell.

MONDAY, JANUARY 24.

ROYAL SOCIETY OF ARTS, at 8.—Textile Ornamentation: A. S. Cole.

VICTORIA INSTITUTE, at 4.30.—The Attitude of Science towards Miracles (being the Gunning Prize Essay, 1909): Prof. H. Langhorne Orchard.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Travels in Northern Arabia: D. Carruthers.

TUESDAY, JANUARY 25.

ROYAL INSTITUTION, at 3.—The Cultivation of the Sea: Prof. W. A. Herdman, F.R.S.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30—Annual General Meeting.—Presidential Address: The Influence of Environment on Man: Prof. W. Ridgeway.

MINERALOGICAL SOCIETY, at 5.30.—On a Group of Minerals formed by the Combustion of Pyritous Shales: S. J. Shand.—A Crystal-holder for Measuring Large Specimens: W. J. Lewis.—Some Observations on Pleochroism: T. Crook.—Notes on the Weight of the "Cullinan" Diamond and on the Value of the Carat-weight: L. J. Spencer.—On a Basalt from Rathjordan, Co. Limerick: G. T. AN AMERICAN AGRICULTURAL CYCLOPEDIA.

Cyclopedia of American Agriculture. A Popular Survey of Agricultural Conditions, Practices, and Ideals in the United States and Canada. Edited by L. H. Bailey. Vol. IV. Farm and Community. Pp. xiv+650. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 21s. net.

DR. BAILEY is surely the most energetic of the agricultural editors of to-day. Besides writing a dozen or more books himself, he has edited a long series of text-books, a great Cyclopedia of American Horticulture, and has now completed the companion Cyclopedia of American Agriculture. So much has he found this task to his liking that he tells us he

> "would like to make another. It is much satisfaction to assemble the opinions of the best men and women in a particular field, and to work them out into a harmonious arrangement."

The subject-matter is not set out under headings in alphabetical order, but is grouped in four great divisions; the first volume dealt with the laying out and organisation of a farm, the second with the crops, the third with the animal products, and in this fourth and last volume we come to

> "the larger question of the relation of the farmer to his fellow men, and of the farm to the other assets of the commonwealth."

This volume, reviewing as it does all those economic, social, and political aspects of rural life which are of never-failing interest, will therefore appeal to a much larger circle of readers than did the others. Most people will be surprised at the magnitude of agricultural industries in the United States. They employ more capital than do all the manufactures put together, and more than one-third of the entire working population, as compared with one-fourteenth in Great Britain. The agricultural exports are larger than any others, whilst the imports form nearly one-half the total imports. Maize is the most important crop, exceeding in annual value any other two combined; further, it is the largest single American product of any kind, agricultural, mineral, or manufactured. A considerable section of the volume is devoted to the history of North American agriculture from Indian times to the present day. Maize has always been the chief cultivated food plant. Jacques Cartier found large fields of it growing in 1534 where Montreal now stands. Champlain in 1604 found it cultivated almost everywhere from Nova Scotia to points far up the Ottawa river. Much was eaten green, generally after it had been roasted or boiled; indeed we may trace not a few of the characteristic American and Canadian dishes to an Indian origin. Beans, pumpkins, squashes, and tobacco were raised by the Indians; fruit was preserved in wild honey; sugar was made from the juice of the maple. An account of this operation can be found in the Philosophical Transactions of the Royal Society for 1684–5 (p. 156), while the Indian maize culture is described in the preceding volume, p. 466. This paper is, as usual, overlooked, probably because it was somehow omitted from the index to the volume. The Indians kept meat in cold storage, *i.e.* in snow, they cured tobacco by heat, they practised irrigation in the dry districts, they cultivated cotton, preserved fruit berries and vegetables by sun and air drying, and they preserved vegetables from rotting by burying them in the ground—the idea of the modern silo.

Coming to historic times, five main periods can be noticed. In the colonial period, 1607–1783, the settlers were adapting and improving on the Indian methods. Next follows the time of the western expansion. From 1830 an enormous change arose in consequence of the introduction of railroads, the repeal of the English corn laws, and the wars and other events in Europe which created a demand for American food products. Lastly, American agriculture has been largely reorganised since 1887, when the Experiment Station Act (Hatch Act) was passed by Congress. Since this time there has been developed that wonderful system of experiment stations and agricultural colleges that is without equal in the whole world. Irrigation and drainage are also attracting attention. It is estimated that there are still eighty million acres of swamp land, not only practically valueless, but a hindrance to travel and a menace to health, which, if properly drained and cultivated, could probably support a population of 10,000,000 people. Various chapters in these historic movements are worked out in considerable detail; we have, for instance, what has probably never been attempted before, a chapter on historic farm animals. Much space is devoted to the present position of agriculture. Various means of checking the rural exodus are suggested, among others that the country schools should teach the love of country life and train for life in the country. Mr. Booker Washington brings out the interesting point that while negroes constitute less than one-twelfth of the population of the United States, they conduct 13 per cent. of the farms, and raise 5·4 per cent. of the total farm products.

Natural resources, especially forestry, receive a good deal of attention. It is shown, too, that the agricultural labourer is very efficient; 9,000,000 hands in the United States raise nearly half as much grain as 66,000,000 in Europe, where, however, far fewer horses are employed. Business organisation, book-keeping, costs, cooperation, and credit are next discussed, while a section is given to the amenities of rural life, the church, travelling libraries and travelling pictures, social organisations, the rural landscape, and "the farm beautiful."

Dr. Bailey himself writes on agricultural education. We notice that the American colleges are subjected to criticism just as are our own, because many of their best students do not become farmers. The answer is, of course, obvious; they are needed to provide the enormous staff of experts maintained by the colleges and experiment stations. The American educational system is more complete than ours in that it aims at giving systematic instruction to the men actually farming. The means adopted include courses at the colleges, reading circles at home, and farmers' institutes. Full details of the working of these schemes are given.

Legislature relating to agriculture is then dealt with, and the somewhat varying laws of the different States are summarised. Lastly, we have a number of biographies of persons who were prominent in developing "agriculture and wholesome country living, and in starting new movements of national consequence."

The volume can be cordially recommended to all who are interested in the remarkable progress of agriculture in the United States. The story is wonderfully interesting, even when told in the rather disjointed manner that is a necessary consequence of a number of authors and an encyclopædia. Problems are arising in parts of the British Empire not unlike those that have arisen in the United States. The methods by which they were dealt with there, which are so well set out in the present volume, cannot fail to afford valuable and suggestive material to agricultural workers and administrators elsewhere.

E. J. RUSSELL.

SIR JOSEPH BANKS.

Sir Joseph Banks, the "Father of Australia." By J. H. Maiden. Pp. xxiv+244. (Sydney: William Applegate Gullick; London: Kegan Paul and Co., Ltd., 1909.) Price 6*s.* net.

IN an old gazetteer we read that Botany Bay was discovered in 1770 by Captain Cook, who so named it from the great quantity of herbs which he found on its shores. This statement is true, of course, as to the main fact, but it is otherwise inaccurate and incomplete, for no doubt the name was suggested by Sir Joseph Banks's report on the vegetation of the country around their first landing-place in Australia and the very rich botanical collections obtained. After circumnavigating New Zealand the question arose whether the *Endeavour* should sail in search of the supposed southern continent or make for the coast of New Holland, and the latter course was determined upon because the condition of the ship was not considered equal to encounter the stormy southern seas. The expedition arrived in the bay on April 28 and left on May 6, and an entry in Banks's journal, dated May 3, runs as follows:

> "Our collection of plants was now grown so immensely large that it was necessary that some extraordinary care should be taken of them lest they should spoil in the books."

This note referred to the collections previously made in New Zealand, as well as the Australian plants, of which, by the way, only a small proportion were herbs.

In commemoration of this notable and important event an obelisk was erected in 1870, the centenary of the landing of Cook and Banks, but it has long been felt in Sydney that Banks's services in the exploration and colonisation of Australia have not been adequately recognised. As Mr. Maiden states in the book before us:—"His journal of the voyage was made over to Hawkesworth, who so arranged the narrative that Banks did not receive due credit." The recent publication of Banks's journal, edited by the venerable Sir Joseph Hooker, has brought to light the prominent part Banks took in the expedition, and the publication now of a portion of his correspondence shows that he was more or less actively engaged during the remaining fifty years of his life in promoting the interests of the young colony and the exploration of the surrounding country. A committee has been constituted in Sydney to collect a fund for the purpose of providing a memorial to Banks. Mr. Maiden has joined the movement, and the book he now offers the public has been compiled with the double object of disseminating information concerning "Australia's greatest early friend" and of procuring a handsome contribution to the memorial fund. It has been printed at the expense of the State of New South Wales, and the whole of the proceeds of the sale will be devoted to the object in question.

That a botanist should have undertaken this task is appropriate, and a botanist living on the spot where Australia's colonisation began, because Banks himself, though a man of universal sympathies, was essentially a botanist and horticulturist. Mr. Maiden has not written a biography of Banks, though he chronicles the leading events of his whole career. Following this he has strung together a chronological narrative of events connected with the early history of Australia, in which many important personages figure besides Banks. The whole is a highly interesting record of facts, gleaned from a variety of sources and selected for the purpose of establishing, or rather vindicating, Banks's claim to the gratitude of both the old and the new countries for the leading part he took in what has proved a most momentous movement in the population of the Antipodes. The book is fully and suitably illustrated, including portraits, early views, and reproductions of Cook's charts of Botany Bay and the entrance to the Endeavour River, on which the modern Cooktown is situated. It is a book, too, that everybody interested in Australia should read, and thereby derive much pleasure, and directly or indirectly assist the author in his patriotic effort. Short extracts from two of Banks's characteristic letters, dated 1797 and 1799, and addressed to Governor Hunter, may close this notice:—

> "The climate and soil are in my opinion superior to most which have yet been settled by Europeans. . . . I see the future prospect of empire and dominion which now cannot be disappointed. Who knows but England may revive in New South Wales when it has sunk in Europe? Your colony is already a most valuable appendage to Great Britain, and I flatter myself we shall before it is long see her Ministers made sensible of its real value."

W. B. HEMSLEY.

THE ESSENTIALS OF THE COMPARATIVE ANATOMY OF VERTEBRATES.

Vergleichende Anatomie der Wirbeltiere. By Dr. Robert Wiedersheim. Siebente Auflage. Pp. xx+936; 476 text-figures, and one lithographic plate. (Jena: Gustav Fischer, 1909.) Price 21 marks.

THE seventh edition of this well-known text-book is much more than a mere reprint of the 1906 edition, the work in its present form having experienced both a thorough revision and a considerable increase in bulk. Additions have been made to the accounts of nearly every system of organs, and the verbal descriptions supplemented by the inclusion of nearly one hundred new text-figures. The new figures illustrating the skulls, so coloured as to distinguish bone from cartilage, are very effective, and those of Petromyzon, Lacerta, Crocodilus, and Chelone will be found especially useful; indeed, it is a pity that a few more laboratory types (such as Hatteria, and some additional birds and mammals) were not included at the same time. The valuable literature-list—a most excellent feature of this book—has also of necessity been much enlarged.

The account of the nervous system shows a marked advance on that of the earlier editions. The description of the internal structure of the brain embodies some of the important results obtained in recent years by Edinger, Sterzi, Elliot Smith, Johnston, and other workers in this branch of anatomy. There is also included a more thorough exposition of the modern component theory of the cranial nerves, though we are of opinion that the sections treating of this subject, and of the primitive segmentation of the head, might with advantage have been still more expanded, both as regards the facts and their theoretical interpretation. The questions, for example, as to the alleged serial homology between ordinary eyes and the paired pineal organs, the primitive sensory nature of the epibranchial placodes (referred to on p. 331) and their possible connection with the eye and the nose, the late origin and consequent non-homology of the acustico-lateral system of nerves with the spinal nerves, the secondary nature of the segmental arrangement of the lateral-line sense-organs, the curious situation of the supposed gustatory organs in the external skin of certain teleosts and their innervation by the visceral sensory lateralis accessorius nerve, are all of intense interest, and worthy of a brief discussion in a book dealing with the fundamentals of vertebrate morphology. The chief results of the large amount of work recently pursued in connection with the gas-bladder of fishes have also been incorporated in the revised account of this subject, though we cannot agree with the unhesitating adoption of the Reis-Nüsbaum idea that the gas contents of the bladder are the product of the chemical decomposition of the substance of the gland-cells; in our opinion Jaeger's view, that the oxygen and other gases are derived directly from the blood and are merely pumped into the bladder cavity by the gland-cells, seems much more feasible. Among other sections of the book which have been considerably altered and extended are those relating to the morphology of the sternal skeleton, the phylogeny of the limb skeleton, the structure of the mammalian lung, the urinogenital apparatus of bony fish, and the male copulatory organs of the chief vertebrate groups.

Concerning what we venture to consider omissions in the book, we must confess that we should like to have seen, among other things, a complete account of the recent work of Osborn, Broom, and others on the Theriodont reptiles, and of the origin of the Mammalia from this ancient group, a subject of intense interest to comparative anatomists and one which has now been worked out in such complete detail that we can trace in these fossil reptilian skeletons the evolution of almost every bone in the mammalian skeleton. Again, the subject of the minute structure of fish-scales, to which Goodrich has recently directed attention, is quite untouched in the present work, though the facts are most striking, both from the standpoints of pure morphology and classification. In saying that these subjects are omissions, and thereby implying that in our opinion they should have been included, we are not unmindful that the size of the book must be kept within reasonable limits; we would only suggest that succinct accounts of the subjects just named and those before referred to are far more suitable for inclusion than descriptions and figures, *e.g.* of the external form of the ear, of the development of the cement organ of Polypterus, of the layers of the retina, and other similar topics which, though also worthy of mention, are of relatively less moment.

We may point out in conclusion that to the best of our belief the common text-book statement (p. 642) that the at-first paired umbilical (allantoic or hypogastric) veins are homologous with the epigastric veins of Amphibia and the lateral veins of Elasmobranchs has been disproved by Beddard: the two sets of veins are quite distinct.

A standard book like the present, and especially this last superb edition, is in no need of recommendation, and our recognition of this is a sufficient apology for the large proportion of criticism contained in the preceding remarks.

W. N. F. W.

THREE TEXT-BOOKS OF PRACTICAL CHEMISTRY.

(1) *A Course of Practical Chemistry Suitable for Public Schools.* By A. Beresford Ryley. Pp. viii+156. (London: J. and A. Churchill, 1909.) Price 4*s.* 6*d.* net.

(2) *Introduction to Practical Chemistry, for Medical, Dental, and General Students.* By A. M. Kellas. Pp. viii+262. (London: Henry Frowde, and Hodder and Stoughton, 1909.) Price 3*s.* 6*d.* net.

(3) *First Stage Inorganic Chemistry* (*Practical*). For the First Stage Examination of the Board of Education (South Kensington). Revised Edition. By H. W. Bausor. Pp. iii+85. (London: W. B. Clive, University Tutorial Press, Ltd., 1909.) Price 1*s.*

AS a general rule, the teacher of practical chemistry yields sooner or later to the apparently irresistible temptation of writing a text-book for the use of students attending his classes. The consequent excessive multiplication of elementary treatises is, in the main, deplorable, although the contents of some of these publications afford an interesting indication of the trend of contemporaneous science teaching.

(1) The course of practical chemistry suitable for public schools is of special significance from this point of view, inasmuch as the author refers to his procedure as a retrogression from the heuristic method, a system which he dismisses as "ideal, but quite impracticable in the larger classes of public schools." This course

of instruction begins with a series of introductory exercises on such fundamental principles as the nature of physical and chemical changes, the common elements and some of their typical compounds, and the processes of combustion, oxidation, reduction, &c. Detailed explanations are to be supplied by the demonstrator, who is also supposed to carry out the more difficult experiments, and to devise the simple apparatus required by the student.

Simple volumetric analysis is introduced at an early stage, but, unfortunately, the underlying principle of equivalence is not adequately explained. Two definitions of equivalent weight are given on p. 54, one referring to acids, and the other to bases and salts. In the latter, equivalent weight is stated to be the molecular weight divided by the sum of the valencies of the metallic radicle. This definition is not applicable to potassium permanganate, an important reagent generally introduced into an elementary course of volumetric analysis. The working instructions for the volumetric analysis and for the determination of equivalents and atomic weights are excellent, and make for neatness and accuracy in quantitative exercises. There are a few singular omissions in the general practical course; formic acid is not indicated as a source of pure carbon monoxide, and although the interaction of copper and hot concentrated sulphuric acid is mentioned thrice, on pp. 13, 92, and 98, no reference is made to the cuprous sulphide which is produced as a bye-product together with copper sulphate.

The last chapter is devoted to qualitative analysis, and contains the practical details of the dry and wet tests for the commonly occurring metals and acids, without equations or other theoretical explanations.

Although an experienced teacher could select, from the large number of practical exercises contained in this treatise, a typical set suitable for an elementary course, yet it would certainly be necessary to add a few simple gravimetric processes such as the estimation of iron, copper, chlorine, or sulphate. Otherwise, the student's practical experience would be sadly lacking in balance, for while having had an opportunity of attempting the preparation of comparatively uncommon compounds, such as phosphine and periodic and bromic acids, he might remain ignorant of the methods of elementary gravimetric analysis.

(2) The author of the second volume under review is of opinion that an elementary practical book should contain more complete explanations than are generally given. This course also begins with the practical study of the non-metallic elements and their typical compounds, but some of this introductory work may be omitted by students who have an opportunity of seeing these experiments demonstrated on the lecture table. The work on the non-metals is followed by the preparation of typical compounds of the metals. These exercises are of special interest to medical and dental students, as a knowledge of the preparations given in detail is required by the syllabus of the Conjoint Board. The list of preparations would be considerably improved by the inclusion of a few double salts (such as ferrous ammonium sulphate and the alums), some of which are quite suitable for an elementary course. The qualitative tests for the metals and acids are described in considerable detail, equations being given for the more important chemical changes, together with a summary relating to each metal and its notable compounds. Although this part of the book is fairly comprehensive, the tests for nickel and cobalt and for boric and hydrofluoric acids are omitted. In other respects, the qualitative analysis is quite adequately treated in a systematic manner, and the tables are remarkably free from errors. On p. 94 the interaction of a silver salt and sodium hydroxide gives the oxide Ag_2O, whereas on p. 148 the product is said to be the hydroxide AgOH. The first reaction on p. 112 refers to stannous sulphide.

The last chapter contains a brief introduction to quantitative analysis, dealing chiefly with volumetric processes.

(3) The third of the foregoing books has been re-written to meet the present requirements of the Board of Education as regards the elementary stage of practical inorganic chemistry. A description of the properties of some common substances leads up to elementary experiments consisting of observational work and simple quantitative exercises. Full working details are given as well as theoretical explanations. The book is admirably suited to the work of the elementary stage.

G. T. M.

OUR BOOK SHELF.

Bathy-orographical Wall Maps of the Pacific, Atlantic and Indian Oceans. (Edinburgh and London: W. and A. K. Johnston, Ltd.) Price 12s. each.

THESE maps of the oceans are on Mollweide's equal-area projection. The elevations and depressions shown are at 6000, 1500, 600 feet, and below sea-level on the land, while 100, 1000, 2000, 3000, and 4000 fathoms are represented over the sea area.

The elevations shown on the land are scarcely sufficient for the purpose for which these maps are undoubtedly intended, the study of the build of continents, but the sea depths should render them useful to teachers.

Many points are admirably illustrated. The oceanic islands are well shown as the culminating summits of ridges, and the use of such maps should help to correct the erroneous notions often prevalent as to the position of island groups.

The complicated series of islands in the Pacific Ocean can only be understood by reference to a clear ocean map. For example, the islands known as Melanesia, which rest on the submarine plateau to the east of Australia, can be seen to have an intimate connection with the mainland, with which they were once connected. On the outer fringe of these islands are the Solomon Islands and New Hebrides, and the Mikronesian group from the Caroline Islands to the Tonga Islands.

Further to the east the South Pacific chain suggests a possible land connection in former ages between South America and Australia, which may account for the migration of marsupial and land tortoises from one coast to the other.

The fringing chains of islands which extend on the north-west of the Pacific from Formosa to Alaska are admirably shown on this map, in contrast to the deep depressions known as the Tuscarora and Aleutian trenches.

The usual classification of the major submarine forms includes the shelf, the depression, and the elevation. The shelf extends to about 100 fathoms below sea-level. As the lowest ground represented in these maps, from 0 to 600 feet, is coloured green, while the sea to the depth of 100 fathoms is tinted a light blue, students will probably find it somewhat difficult to compare these areas. The maps would have gained considerably if both these regions, from 600 feet to the 100-fathom line, had been left white, and if the names, at any rate on the land, had been omitted. It is surely quite unnecessary to print "Africa" across the continent in such large letters as to obscure some of the details of the plateau of Abyssinia.

On the oceans the names are fewer in number, and do not interfere with the graphic effect of the deeper blue which marks the depressions and elevations of the ocean floor.

Though, as regards graphic representation, more suited for reference than school use, these maps have one important advantage. The equal-area projection employed is most effective for the oceans, when shown separately, and the comparison of areas possible should be useful in the study of the relative extent of land and sea.

The Practical Management of Sewage Disposal Works. By W. C. Easdale. Pp. 60. (London: The Sanitary Publishing Co., Ltd., 1909.) Price 2s. net.

The author has endeavoured with considerable success to deal, in the space of fifty-four small pages, with the more important points arising in the management of small sewage works and private-house installations, &c.

When considering the question of tanks, the author rather unfortunately states that in all types of tanks, *i.e.* sedimentation, precipitation, and septic tanks, the work to be done is the same, viz. the removal of suspended matter. This expression is somewhat misleading and liable to misinterpretation.

Apparently, in dealing with the removal of sludge from tanks, septic tanks only are considered, as the author's doctrine of "little and often" removal, without emptying the tank, can only in general be properly applied to such tanks, and, it may be added, only when the design of the tank allows of the removal of the more or less thoroughly septicised sludge. In the case of sedimentation and chemical precipitation tanks, it is almost essential that the sludge should be completely removed at each operation in order to avoid fermentation taking place, with its consequent ill-effect on the complete settlement of the suspended solids.

In connection with the design of contact beds, the author rightly directs attention to the extreme importance of the thorough and complete drainage of the bed, and also to the question of the size of the unit.

It is evident that there is a limit to the application of the maxim "little and often" advocated in regard to the removal of accumulated suspended matter from the surface of the contact beds. From the point of view of economy, cleansing operations should not be carried out too frequently, as it is obvious that a certain amount of filtering media must be removed at each operation, incurring additional cost; while so long as the accumulated suspended matter is not sufficient to impede the drainage from the surface and consequent ingress of air, no detrimental results may be anticipated.

The author's remarks with regard to the attention to be given to distributing apparatus in connection with percolating filters are important, and should be carefully noted. In connection with the final chapter on tests and records, Spitta's methylene blue test might with advantage be included, and possibly a colour test for nitrates.

The book can be thoroughly recommended for the objects defined in the author's introductory remarks.

E. A.

Das Reich der Wolken und Niederschläge. By Prof. Dr. Carl Kassner. Pp. 160. (Leipzig: Quelle and Meyer, 1909.) Price 1.25 marks.

This work, No. 68 of the popular scientific manuals published by Messrs. Quelle and Meyer, is to some extent the outcome of lectures delivered by the author at technical high schools, modified to meet the requirements of general readers. In addition to sound elementary information on the taking and reduction of observations, it includes the results of the most recent investigations, of the fundamental researches of Hann, Hellmann, and others, and useful references to the historical development of this branch of meteorological science. Chapters i.–v. treat of aqueous vapour, condensation, formation of fog and clouds, sunshine and cloudiness. Chapters vi.–x. deal with rainfall, snow and hail, exposure of gauges, calculation of results, &c. The remaining chapters, xi.–xiii., refer to the rainfall over the globe, the causes of its unequal distribution, to daily, yearly, and secular periods. The whole will repay careful perusal; among some of the many points of special interest we may note references to Goethe's appreciation of Howard's classification of clouds, to various kinds of glazed frost and hail, and to the effect of wind and exposure on rainfall records. Hellmann's classification and reproduction of Neuhauss's photographs of snow crystals are preferred to Glaisher's drawings, which the author hints should now be omitted from text-books. On p. 78 we notice that Chepstow is misprinted as Chepston.

Astronomische Abhandlungen der Hamburg Sternwarte in Bergedorf. Edited by the director, Dr. R. Schorr. Band i. No. 1, pp. 130, and 3 plates; No. 2, pp. 10, and 3 plates; No. 3, pp. 99. (Hamburg, 1909.)

Founded in 1825 by State-aided private means, the Hamburg Observatory was taken over by the State in 1833, and in 1906 was by decree transferred to the new site at Bergedorf. This site and its equipment are briefly described in Dr. Schorr's introduction to the new series of "Abhandlungen" of which that under review is the first volume.

Part i. is by Dr. Dolberg, who describes, and discusses, the latitude determinations made at Hamburg in 1904–6. The observations were made with a Repsold portable transit instrument, and a great part of the time was spent in determining and discussing the instrumental errors. The actual latitude observations were made in 1905, and consisted of 426 complete measures of 90 pairs of stars. These are discussed, with the reductions, at length, and a mean latitude of $53^\circ\ 33'\ 6{\cdot}05'' \pm 0{\cdot}015''$ is found for the position of the circle.

Dr. Graff is responsible for the work described in parts ii. and iii., and in the former he describes his observations, measures and drawings of Saturn during 1907, when the ring system and the earth lay in the same plane. The three plates carry twelve drawings, and form an interesting record of the various appearances of the edges of the rings from July 26 to November 30, 1907.

Part iii. is of less general interest, but is a useful reference work. It contains the places of 580 variable stars, lying between the North Pole and 23° south declination, for the epoch 1900·0. The objects are given under their various constellations first, and are then collected into a general catalogue showing the number, the name, the maximum magnitude, the coordinates for 1900·0, the precession, and the B.D. number for each star.

The volume is in quarto form, neatly and strongly bound, and altogether promises the addition of a valuable series to current astronomical publications.

Upper-air Temperatures Registered Outside and Inside Balloons

Attention has been directed several times in Nature to the interest attaching to the knowledge of the rate at which the gas inside rubber balloons takes up the temperature of the air outside. In this connection the results of two registering-balloon ascents from Manchester, made at the suggestion of Mr. Gold, are useful as giving some idea of the magnitudes of various possible errors.

The ascents were made on July 2, 1909, at 6.50 a.m. and 10.17 p.m. respectively. Each balloon carried two instruments, of which one was suspended in the usual manner about 4 metres below the balloon, while the other was fixed inside the balloon. The latter instrument was kept approximately in the centre of the balloon by means of rubber stays. The results are given in the following tables :—

Table I.—(6.50 a.m. *Ascent.*)

Height (ks.)	Temperature °C.		
	Instrument outside Balloon.	Instrument inside Balloon.	
		Ascent.	Descent.
0	10·8	16	12
1	7·0	16·5	7
2	+ 4·5	15·5	+ 5·5
3	− 0·5	13·5	− 0·5
4	− 6	10	− 4
5	− 12·5	4·5	− 13
6	− 19	+ 1·5	− 18
7	− 24·5	− 1·5	− 23·5
8	− 31·5	− 6·5	− 31·5
9	− 39·5	− 9·5	− 38·5
10	− 44	− 14	− 44
11	− 45	− 15	− 47·5
12	− 44	− 13·5	− 49
13	− 43	− 10	− 48·5
14	− 41·5	− 6	− 47
15	− 39·5	− 2·5	− 42·5

Table II.—(10.17 p.m.)

Height (ks.)	Temperature °C.	
	Instrument inside Balloon.	
	Ascent.	Descent.
0	11·5	10
1	+ 2·5	+ 6
2	− 0·5	− 0·5
3	− 6	− 6
4	− 11	− 11
5	− 17	− 17
6	− 23	− 23
7	− 28	− 31
8	− 34	− 38
9	− 40·5	− 44
10	− 48	− 50
11	− 55·5	− 56
12	− 55·5	− 57·5
13	− 56	− 58·5
14	− 57·5	57·5

The traces of the two instruments sent up at 6.50 a.m. emphasise the large possible error arising from insolation should the vertical velocity of the balloon fall below the value necessary for efficient ventilation. The temperatures recorded during the ascent diverge as the height increases, the maximum difference—nearly 40° C.—occurring at the maximum height attained, *i.e.* 15 km. That the divergence is not due to a systematic difference between the two instruments is shown by their good agreement during the greater part of the descent. In this connection it is of interest to compare the experimental results with the mathematical computations made by Mr. Gold in Nature, March 18, 1909, p. 68.

Substituting in his equations the values corresponding to the Dines instrument and the small rubber balloons employed in the ascent, and assuming that half the incident solar radiation is absorbed, we find that $(T-\theta)$, the temperature difference between the gas inside and the air outside, may be 20° C. This is considerably less than the actual value found (30° C.), but the discrepancy is easily explained by the fact that the radiation which penetrates the semi-transparent envelope strikes the almost unventilated instrument inside. That this accounts partly for the difference is evidenced by the fact that the temperature ceases to fall near 11 km., where the pressure is about 150 mm., *i.e.* the pressure below which the natural convection has been found to be ineffective.

The night ascent gives more definite information. The trace of the outside instrument in this case was defective, and it was assumed that the descent readings of the inside instrument gave a close approximation to the readings of the outside one. The doubling of the trace at low altitudes is due to the high initial temperature of the gas inside the balloon—that of the laboratory in which it was filled—and to the effect of daily variation of temperature during the time interval between the beginning of the ascent and the end of the descent. From 2 to 6 km., however, the temperature inside the balloon is the same as that of the outside air. At about 6 km., where there is a considerable increase in the temperature gradient, a lag is developed, which increases to about 8·5 km. where the temperature difference reaches 5° C. Subsequently the lag steadily diminishes, and at 10·5 km. the temperatures are again in agreement to within 1° C. Applying Gold's equation to this case, we find, on substituting the values appropriate to the ascent, that the theoretical lag at 11 km. is about 0·7° C., a rather remarkable agreement in consideration of the fact that the equation is admittedly only approximate. It would appear, therefore, that what might be called the "natural" lag of the balloon temperature in night ascents is small, and that the lag indicated between 6 and 11 km. arose from special circumstances possibly connected with the humidity of the air. The difference between the ascent and descent traces above 11 km. may possibly be attributable to the same cause as the divergence from 15 to 10 km. of the descent traces of the two instruments employed earlier in the day. The results demonstrate conclusively the very large effect of solar radiation compared with that of terrestrial radiation, and indicate that errors in temperature due to air which has already been in contact with the balloon and to radiation from the balloon are, in night ascents, negligible.

In the daytime, however, errors arising from these causes may be considerable. This may, in fact, explain why the differences between the upward and downward traces in ascents by day are more frequent and of greater magnitude than those found for night ascents.

Avogadro's Hypothesis.

I should like to direct the attention of Mr. Woolhouse (Nature, January 20) to the little book "Avogadro and Dalton, the Standing in Chemistry of their Hypotheses" (Edinburgh: W. F. Clay, 1904), in which Dr. Meldrum discusses with great force and discrimination the exact position which should be given to Avogadro's hypothesis. Dr. Meldrum also deals faithfully with those who have made light use of the word "law."

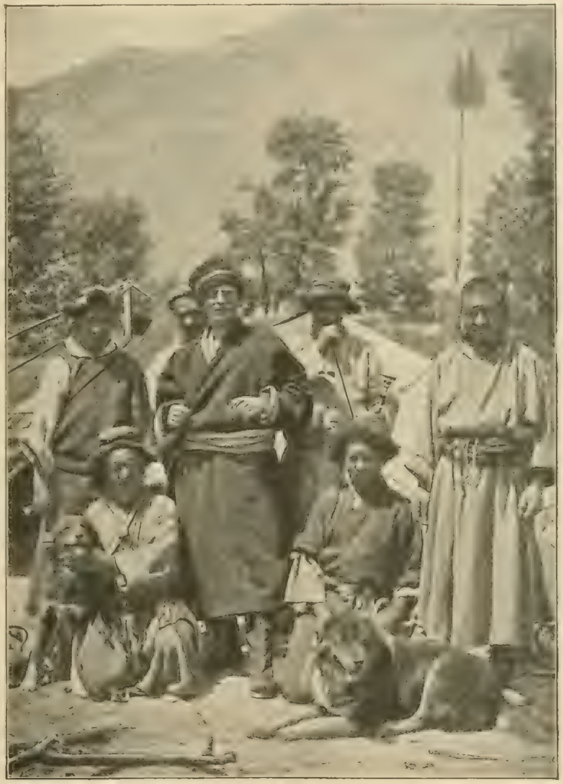
SVEN HEDIN'S "TRANS-HIMALAYA."[1]

THE special quest of Dr. Sven Hedin in his last and greatest journey of geographical exploration in Tibet was that hitherto unexplored range of mountains, which was believed to rise within the unsurveyed white patch of desert on the "Roof of the World" to the further side of the Tsangpo or Brahmaputra, behind the Himalayas. Although this immense chain, stretching for about 600 miles, is one of the mighty mountain ranges of the earth, and forms the northern watershed of the great Brahmaputra, as well as of the Upper Indus, yet its very existence, even, was largely the subject of conjecture.

A line of high peaks in this desolate region was first reported about 200 years ago by a party of surveyor-Lamas, who had been trained and sent out into Tibet by the Jesuits of Peking, under the patronage of the emperor, Kang-hsi; and the peaks, as located and named by these Tibetans, and rediscovered by recent travellers, figure on the rough map, published by D'Anville, in A.D. 1733. Brian Hodgson, in 1848, as the result of his inquiries in Nepal, depicted these peaks in his sketch-map as forming portions of a hypothetical range of mountains, stretching continuously from the Karakorum and Pamirs on the west to the Tengri Nor lake near Lhasa on the south-east; and he assigned to it the name of "Nyenchen," after the name of the highest peak near its Lhasa end. In the map attached to Huc's travels, this range is also represented as an unbroken chain; and so, too, in Saunder's map of 1879 in Markham's "Tibet"; whilst Grenard, the companion of the ill-fated de Rhins, in 1899, indicates it conjecturally as a double range, which Colonel Burrard, of the Indian Survey, in his recent book on the geography of Tibet, has called the "Kailas Range," after the famous Mount Olympus of the Hindus, at its northern end. So great, indeed, was the need for the exploration of these mountains deemed to be that the president of the Royal Geographical Society declared a few years ago that: "In the whole length, from the Tengri Nor to the Mariam La, no one has crossed them, so far as we know" (a statement, by the way, not absolutely correct, as the pundits Nain Sing and A-K. and Littledale had crossed them) " . . . . I believe *nothing in Asia is of greater geographical importance than the exploration of this range of mountains.*"

This, then, is the range to which Dr. Hedin now assigns the appropriate name of "Trans-Himalaya," after having zigzagged across it by eight different passes, and after mapping out its contours in considerable detail.



Sven Hedin.

FIG. 1.—The members of the last Expedition in Poo. From "Trans-Himalaya."

More than this, the two handsome volumes in which Dr. Hedin tells the story of this great achievement differ from all his previous books on the "Forbidden Land" in possessing greater human and living interest. For the first time, after his many previous years of travel in that country, he has been able to penetrate beyond the desolate deserts and reach a portion of what he truly terms "*Tibet proper*, that is the part chiefly inhabited by a settled population." For this good fortune and for the more friendly treatment generally which he experienced at the hands of the Tibetans he is indebted directly to the amicable relations established with Tibet by the British mission of 1904, none the less real and genuine though cultivated at the point of the bayonet. These relations of friendship and respect, strengthened and cemented by the visit of the Grand Tashi Lama to India in 1905 to meet the Prince of Wales, have enormously increased the prestige of the European throughout Tibet and Central Asia. Thus, a section of Younghusband's mission with four British officers, unaccompanied by any escort of their own, but relying solely on the protection of the Tibetans, was able to pass in a friendly way through those inhabited districts of Tibet, two years before Dr. Hedin visited them; and several other Europeans have visited the Tashi Lama's palace and the western capital. In particular, Lord Minto, the Viceroy of India, to whom the author gratefully dedicates his book, "used his influence with the Tashi Lama so that many doors in the forbidden land formerly tightly closed were opened to me."

---

[1] "Trans-Himalaya, Discoveries and Adventures in Tibet." By Sven Hedin. With 388 illustrations from photographs, watercolour sketches and drawings by the author and 10 maps. In 2 volumes. Vol. i., pp. xxiii+436; Vol. ii., pp. xvii+441. (London: Macmillan and Co., Ltd., 1909.) 30s. net.

The start, under such favourable conditions, was made in August, 1906, from Ladak, by way of Kashmir, as the recent treaty with China absolutely prohibited Europeans entering Tibet across the Indian frontier, and could not be relaxed by the Indian Government even in favour of Dr. Hedin, much to his freely expressed vexation. He gave out that he was proceeding to Turkestan, but in the solitudes, a few marches out of Leh, he crossed the lofty Karakorum range and turned southwards into the great elevated Tibetan desert, the Chang-tang. Here he pushed on through the stark solitudes, day after day for two months, surveying the country, without meeting a soul until he crossed the Trans-Himalaya near the capital of Western Tibet. The first nomadic herdsmen he encountered were friendly and acted as guides and supplied provisions and baggage animals. They, as well as their chief, informed him of the friendly passage that way of the British officers saying that "now Europeans seem to be privileged to pass through the country." In a few days more, Tibetan couriers arrived with his European letters, which had been sent on by the British agent through the Tashi Lama, at the request of Lord Minto; and accompanying these letters, were welcome stores of European provisions, newspapers, books, &c., as presents from the British agent at Gyantse; and, most important of all, an official to guide and assist Dr. Hedin through that inhabitated portion of Tibet to the Tashi Lama's capital.

Thereafter, writes our author, "the route was as free to us as the uninhabited Chang-tung had been. We should pass black tents daily, be able to buy all we want. We enjoyed unlimited freedom, and had not a single man with us as escort or watchman." Arrived at the capital, Shigatse, he says, "the priests welcome us with kindly good-tempered smiles," and he was installed as the favoured guest of the Tashi Lama, the second of the "Living Buddhas," who received him cordially several times. This high honour which he procured through Lord Minto, proved so invaluable to Dr. Hedin, that, as he writes, "eighteen months later it came about that chiefs and monks said *Bonpo Chimbo* [great lord!] we know that you are a friend of the Tashi Lama, and we are at your service!" His Holiness, it is interesting to learn, has been a keen photographer since his visit to India, when he was initiated into the mysteries of the art by British officers. In his palace he has had a dark room fitted up, where the developing is done by one of the young priests who accompanied him to India. Whilst halting at the Tashi Lama's capital, our traveller lightened his baggage by sending back to Europe, through the British officer at Gyantse, his survey records, note-books, photographic plates, rock-specimens, &c. Here, also, he witnessed the new-year's carnival and festivities, and was allowed to roam freely over the famous palace of the monastery of the Tashi Lama, a busy hive of four thousand ascetics; but, unfortunately, our author, through want of special knowledge, has not added anything to our information on these interesting subjects.

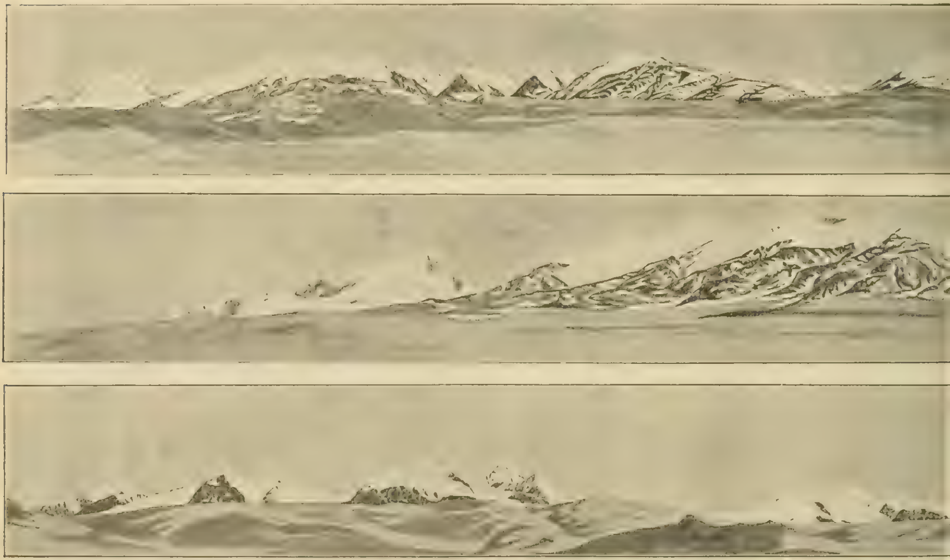


FIG. 2.—The Summits of Lunpo-Gangri from three Camps. From "Trans-Himalaya."

His stay at Tashilhunpo was brought suddenly to an end by the Chinese officials at Lhasa, who insisted on the Tibetans enforcing the treaty, so that Dr. Hedin was compelled to return forthwith to Ladak under a guard. On the way, he succeeded in eluding his guard and made a detour across the Trans-Himalaya by two fresh passes; he also discovered a new western source of the Brahmaputra, and took a series of soundings over Lake Manasarowar, by means of his portable boat.

On return to Ladak, with characteristic pertinacity, he decided to make a second expedition back again to Tibet, in order to complete his partial exploration of the Trans-Himalaya, as he reflected that, "it was especially irritating to think that others might come here and rob me of these conquests." So with a fresh caravan, got together with the aid of the British officials, he plunged south once more through the terrible Tibetan deserts, and much astonished the discomfited Tibetan chiefs by his reappearance amongst them a year after they had got rid of him with such infinite pains. In this latter traverse, three more passes were surveyed, with the result, to quote the author's own words, that, "When I passed over the Trans-Himalaya for the eighth time at Surnge-la, I had the satisfaction of seeing all the old hypotheses fall down like a house of cards and a new ground plan laid down on the map of Asia, where before the blank patch yawned with its alluring 'Unexplored.'" This mountain-system, it is remarked, cannot be called "a range," because it is a collection of several ranges, more or less parallel or branching off at various angles; Dr. Hedin, however, will find that somewhat similar features are displayed by the Himalayas themselves.

The narrative of the two years' strenuous journeyings for the survey of these formidable mountains, is written in a vigorous, direct, style, which reflects the cheery optimism of this pioneer traveller as he pushed on undaunted, in the face of endless hardships and difficulties. It also shows him animating his men with something of his own abounding enthusiasm, without which, indeed, the exploration could never have been accomplished. The reader feels the swing of the caravan moving through the pages, with the thrill of reality and a pervading sense of danger ahead; though to many readers the repetition from day to day of the details of camp routine, and the reiterated records of the grim struggles of the men and the sufferings and painful deaths of the dwindling baggage animals, will doubtless make somewhat monotonous and unpleasant reading after a time.

Besides the geographical record, so important in itself, and the camp episodes, there is little else that is new. Remarkably few references occur in respect to natural history; scarcely any mention or passing recognition is made of wild animals, or plants, or minerals, such as we expect in the journal of a scientific traveller; and the few remarks which occur in regard to the people and their customs exhibit a lack of familiarity with authentic sources of precise information, and the well-known researches of Rockhill and others. Incidental reference is made to a collection of rock-specimens, the description of which by specialists, is promised along with the detailed maps, which will doubtless be accompanied by an analysis of other objects collected, though no mention is made of them. The young Indian elephant of the Tashi Lama, we are told, "is the only one of his species in the whole country"; but the Talai Lama, we know, has (or had in 1904) a much larger tusker, a present from the Sikhim raja, which had survived the arctic winters of many years at Lhasa, and was housed in a grove near the British mission camp outside that city in 1904. "A *Bod* or Buddhist" is spoken of as if these two terms were equivalent, whereas the former means a Tibetan or inhabitant of *Bod* or Tibet. The "*Bothiyas*" (*sic*) are described as "a mixed people sprung partly from Indian and partly from Tibetan elements," whilst in reality, "Bhotiya" is merely the Indian designation of the Tibetan race or people of *Bod*. A want of precision in the spelling of several of the vernacular place-names is noticeable in a professedly geographical work, thus "Sekiya" invariably occurs in the text for the well-known monastery and sect of Sakya or Saskyas, and "Yere-tsangpo" for the Yaru (or "upper") Tsangpo; and many of the names are spelt phonetically according to no regular system. To say "Hor or Bod-yul" is equivalent to saying "Turkish or Tibet." In regard to the term used for the great Manasarowar Lake by D'Anville in his old map, namely "*Ma-pama Talai,*" or Ma-pama Lake, Dr. Hedin gives "Ma-vang" as the correct form, but this latter is merely the vulgar vocalization of the name, which is spelt and properly pronounced as "*Ma-pàm*"; and our author sagely states that "D'Anville might have added that the Chinese and Talai or Dalai means ocean," and that it was used to imply that this particular lake was larger than the other neighbouring lakes mentioned in his text. This, however, is not correct; "Tālai" is *not* Chinese, but a Mongol word, and it is applied to all the lakes in that neighbourhood, as well as throughout the Northern Himalayas, irrespective of their size; and in the abbreviated form of "*Tāl*" it was imported into Northern India by the Moghal section of the Mongols, and is now naturalised there as the current vernacular name for a lake. Deficiencies of this kind, however, can be corrected in another edition, and in no wise belittle the outstanding importance of Dr. Hedin's splendid geographical achievements.

These attractive volumes, with their wealth of sketches and beautiful photographs, deserve nothing but praise, and form a fitting record of Sir Sven Hedin's magnificent pioneer work amongst one of the most forbidding mountain ranges in the world. This work, too, is of such importance to Indian hydrography as to have gained for its author, amongst other well-earned honours, a knighthood of the Indian Empire. It is also pleasing to observe that his men have not been forgotten, for the thirty-seven Asiatics who followed the explorer faithfully through Tibet, and, as the author generously admits, "contributed in no small degree to the successful issue and results of the expedition," have been rewarded with gold and silver medals, bestowed by the King of Sweden.

COLOUR-BLINDNESS.

FOR a considerable time past dissatisfaction has been felt in certain quarters with the methods adopted by the Board of Trade in examining in colour-vision candidates for certificates as master or mate in the mercantile marine. On June 30, 1909, Lord Muskerry directed attention to the matter in the House of Lords, using the cases of Mr. W. H. Glover and Mr. John Trattles as the text of his argument, and moving that a Select Committee be appointed to consider the conditions under which eyesight tests for the mercantile marine certificates were conducted. Lord Hamilton of Dalzell, in reply, stated that during the last four years 25,151 candidates were examined; of these 239 failed in the colour-vision tests; 64 appealed, with the result that 27 passed and 37 were rejected. The tests, based upon the report of a committee of the Royal Society, which sat at the request of the Board of Trade in 1890, were considered to be efficient as at present carried out. He held that no case had been made out for the appointment of a Select Committee. The Marquis of Salisbury said he had, perhaps, a special claim to be heard in this matter, because he was colour-blind himself. He was convinced that colour-blindness was capricious; on some days he was very much more colour-blind than on other days. But from the point of view of the Board of Trade and of the mercantile marine such caprice must be very dangerous. The motion was by leave withdrawn.

Since this debate in the House of Lords the case of Mr. John Trattles has assumed greater importance, and it will be well to recount briefly its history and the chief features which it presents. In February, 1904, Mr. Trattles was examined for his certificate as second mate; he passed the colour-vision test, and was granted his certificate. In July, 1905, he went up for examination as first mate, and failed in the colour-vision test. He appealed, and was specially examined by Sir William Abney and Captain Harvey, and again failed. In September, 1905, having refused to surrender his certificate as second mate, a Local Marine Board was called to inquire into his competency. The board found that he was not incompetent to hold his certificate by reason of colour-blindness. In May, 1906, he was examined for a certificate of competency as first mate; he passed the examination, including the sight-test. The Board of Trade was not satisfied, and, after some correspondence, he was offered and accepted a special examination by Sir William Abney and Captain Harvey. It took place in May, 1909, when he again failed in the colour-vision test. He declined voluntarily to surrender his second mate's certificate, and the Board of Trade instituted a special court, consisting of Sir Francis Mowatt, president, with Mr. J. Dickinson, stipendiary magistrate, as legal assessor, to decide the issues. Mr. Trattles therefore came before this court after six examinations in colour-vision during the last six years; on three occasions he passed, and on three occasions he failed.

On the occasion of the special examination by Sir William Abney and Captain Harvey in May, 1909, owing, presumably, to the agitation in the medical and lay Press against the methods adopted by the Board of Trade, certain scientific bodies were invited to send representatives to witness the tests. Dr. W. H. R. Rivers, F.R.S., lecturer in the physiology of the senses in the University of Cambridge, and Mr. J. Herbert Parsons were present, representing the Royal Society and the Ophthalmological Society respectively. These gentlemen were not informed that the case was one likely to render desirable their evidence as witnesses in a court of law. Dr. W. Ettles, who had examined Mr. Trattles, and was of opinion that he was not colour-blind, was also present.

The special court commenced its sittings on December 2, 1909, at the Imperial College of Science and Technology, South Kensington. Evidence was given by Sir William Abney, Dr. Rivers, Mr. Herbert Parsons, Captain Harvey, Captain Fulton, and Fleet-Surgeon Prynn, R.N.; they concurred in their opinion that Mr. Trattles was colour-blind. Mr. Trattles's witnesses included himself and several well-qualified captains, who had had extensive experience of his skill and ability in navigating ships under conditions of difficulty in the North Sea, the Baltic, the Channel, the Atlantic, the Mediterranean, the Black Sea, and in the Mersey. We do not notice the name of Dr. Ettles in the reports we have seen; we should have thought that he would have been an important witness for the defence. Mr. Trattles submitted to an examination before the court, conducted by Sir William Abney. The court further allowed a practical test, conducted by Commander Wilson-Barker, R.N.R., who was nominated by the Trinity House Brethren. It took place on the evening of December 30, when it was "calm, with some haze on the horizon." Commander Wilson-Barker reported that "Trattles had no difficulty whatever in picking up the lights. He had vision of a quality equal to that of myself and of the look-out man." He instanced two tests to which he attached special importance. On approaching the Nore light at some distance off, Trattles hesitated, questioning if it was not a reddish light. He was correct, the light being a new white light in which some ruby rays are retained as an experiment in penetrating the fog. Trattles was asked to describe the colour of two planets which the Commander pointed out to him from the deck; he did not recognise them, but he correctly described one of them (Mars) as reddish. Sir Francis Mowatt came to the conclusion that Trattles is not incompetent from colour-blindness to discharge the duties of a mate, and directed that his certificate as second mate be returned to him.

We have quoted this case at considerable length because, in our opinion, it demonstrates beyond dispute the urgent need of reform in the methods of conducting inquiries into the colour-vision of candidates by the Board of Trade. Here is a man, with an unimpeachable record in his profession, whose life must have been made a misery from anxiety as to his future career. On the other hand, the public cannot but feel perturbed at the thought that numberless lives are endangered if mistakes are allowed to occur. There are obviously two explanations of the anomaly that the same man may be rejected by the same tests conducted by different examiners; either the tests themselves are at fault or, if efficient, they are not applied with sufficient care or accuracy. Experts whose opinions cannot be lightly disregarded will be found to support both these contentions. For our own part, for reasons which it would take too long to enter into on the present occasion, we incline to the second alternative. The preliminary examinations are conducted by men who have no knowledge of physiology, whatever their other qualifications may be. Even on appeal there is no physiologist amongst the examiners.

We do not wish to labour this point unduly, but owing to the manner in which it has been neglected in the past it merits serious consideration. Defects of colour-vision are defects of a physiological condition, and belong to the class of conditions which the physiologist is accustomed to deal with. Every physiologist to-day must perforce be a more or less accomplished physicist; every physicist is by no means called upon to be an equally accomplished physiologist. The physiologist is familiar with those tantalising variations which characterise living matter, induced by the lability of the medium and the complexity of the forces brought to bear upon it. Even amongst physiologists and ophthalmologists, only those who have devoted particular attention to this highly specialised branch are fully qualified to deal with it. Normal colour-vision shows a great range of variations under differences of intensity of stimulation, differences of adaptation of the retina, differences of the psychological condition, and in different individuals. To take a simple example, the fields of vision for colours vary according to the intensity of the stimulus. Defects of colour-vision show an equally wide range, and whilst it is possible to group the cases according to certain well-defined types, there is none of that accuracy of definition in the scientific picture which rejoices the heart of the physicist. Whilst comparatively gross tests, such as the ordinary tests with Holmgren's wools, used in preliminary examinations by the Board of Trade, suffice to distinguish the graver forms of defective colour sensation, they cannot, as ordinarily applied, be regarded as infallible in less pronounced cases—cases which may yet involve danger to many lives if they are allowed to pass unrecognised. Hence occurs the necessity for more delicate tests, physical indeed in their nature, but only to be interpreted accurately in the light of a comprehensive knowledge of the physiology of vision.

We have the profoundest respect for the work which Sir William Abney has done upon the subject, and every competent critic will endorse the opinion of Lord Rayleigh, quoted by Lord Hamilton of Dalzell, that the Board of Trade could not be wrong in following his advice. How is it to be explained, then, that his opinion, endorsed by other competent men of science, is not accepted as final? We think that it is largely due to the difficulty, or rather impossibility, of conveying to laymen any adequate conception of the peculiarities of vision of the colour-blind. The difficulty is enhanced by the terminology and phraseology adopted by the expert, who almost invariably speaks, as it were, in the language of the theory of colour-vision which he personally affects. Thus, Sir William Abney describes a man in terms of the Young-Helmholtz theory as *red-blind,* whilst Dr. Rivers, agreeing entirely with the facts of the colour-vision of the individual, describes him as *red-green-blind,* and would doubtless prefer to avoid all ambiguity by calling him scoterythrous. Every statement which either might make in endeavouring to convey some idea of the visual perceptions of a colour-blind individual to one who has had no training in the physiology of the senses might be implicitly relied on for accuracy when rightly interpreted, but the probabilities of correct interpretation are exceedingly small, if, indeed, the whole statement is not regarded as a meaningless jargon.

Further, the layman fails wholly to understand why recondite tests, such, for example, as that with simultaneous contrast colours, should be imposed upon the examinee. He can comprehend "practical" tests on board ship, such as that to which Mr. Trattles submitted. It would surprise him greatly to be told that under favourable atmospheric conditions the expert would fully expect a colour-blind person to pick up lights with unfailing accuracy.

The Trattles case will have served an invaluable purpose if, as must inevitably be, it focusses public opinion upon the glaring anomalies of the examination in colour-vision of candidates by the Board of Trade. It appears to us to be imperative that all the conditions should be re-investigated by a competent body, either a carefully selected Royal Commission or a committee of the Royal Society upon which physiologists and ophthalmologists who have devoted special attention to the subject are adequately represented. Among the duties of such a committee would be:—

(1) Re-investigation of the tests for colour-blindness with the view of the adoption of methods less open to attack, and, if possible, of a simpler nature.

(2) Re-organisation of the examinations and of the boards of examiners.

We have no doubt that it would be possible so to revise the conditions of the Board of Trade examinations that it would cease to be necessary to have recourse to a court of law for adjudication on the results of a purely scientific question.

NATURE PHOTOGRAPHY.[1]

THE object of Mr. Bedford's book is to encourage the pursuit of nature photography among those who cannot afford either the time or expense to undertake very advanced work in this direction. The author rightly points out that there are great advantages in this method of studying nature over the older method of collecting, and that the study of natural history by means of photography may be taken up by those whose time and means are strictly limited. The first part of the book deals with the apparatus required. A detailed description is left to text-books on photography; some knowledge of cameras and photographic methods is assumed, and the author confines himself to suggestions and to an account of the particular kinds of apparatus which he himself has found serviceable. On the whole, this part of the book should be valuable to a beginner taking up the subject for the first time, but one feels that in some parts space is wasted in describing processes of which a sufficient account is given in every book on photography, and other parts might with advantage be made more full, for in places the reader is left with no clear idea of the nature of the instrument or process recommended. Rough estimates of cost might also have been included; several times we are told that the choice must be decided by the possible outlay, but no actual estimates of expense are given.

The second part of the book deals with the actual photography of living objects. In the chapter on choice of subjects, the author very rightly emphasises the fact that a connected series of photographs of one subject or group of subjects is of much greater interest and value than an indiscriminate collection of pictures of isolated things. This is illustrated in the book by the series of plates (Figs. 69–76) showing the early life of a young cuckoo. We regret that the chapter was not extended somewhat, at least so far as to emphasise the value of photographic records of objects which cannot easily be collected or preserved in their natural condition, such as fungi, insect larvæ, or fruits. As an illustration of the excellent results that may follow from the patient collection of photographs of such things, one may mention Connold's useful book on "British Oak Galls."

Red Admiral Butterfly (wings expanded). From "Nature Photography for Beginners."

The chapters on how to observe and photograph the commoner birds and their nests take the form of a conversation, or rather discourse, to an imaginary novice during a series of birds'-nesting excursions. This style of writing is very irritating, as are the frequent references to the pleasures of tea in the country, and these chapters might lead one who had never searched for nests to believe that one could be found in every bush in which it was sought. It is to be regretted that the author did not put his evidently considerable knowledge of nesting-habits into different form. The succeeding chapter, on curious nesting-places, where the author's experience is told straightforwardly, is much better. The concluding chapters, on photographing animals and flowers and on protective colouration, are so sketchy as to be of little practical use, and we note some mistakes, *e.g.* the statement on p. 161 about the cause of colour differences in moths probably has no foundation.

---

[1] "Nature Photography for Beginners." By E. J. Bedford. Pp. xiv+168. (London: J. M. Dent and Sons, Ltd., 1909.) Price 7s. 6d. net.

The style of the whole book is colloquial, and sometimes marred by not very successful attempts at wit.

The book is illustrated by a number of very pretty photographs, which are distinctly good, but not of the striking character made familiar by some other nature-photography works. Nearly all are stereoscopic, and a stereoscope is supplied with the book which adds considerably to their usefulness. Unfortunately, the stereoscope makes the texture of the process-block unpleasantly conspicuous. Although the photographs are not especially striking, they illustrate well the kind of work which an amateur who is limited in time or means may hope to produce.

THE NEW COMET (1910*a*).

THE comet discovered near Johannesburg on January 16, as announced in last week's NATURE, has justified the opinion then expressed as to its becoming a brilliant object in our evening skies. From many parts of the civilised world we hear of crowds gathering to watch the rare phenomenon, and the daily Press, despite the General Election excitement, has devoted considerable space to the description of the "Daylight Comet."

Apparently the comet was first seen by some miners on January 16, and reported to Mr. Innes, of the Transvaal Observatory, Johannesburg. Messrs. Worssell and Innes made the first measurement of its position at 19h. 29·2m. G.M.T. January 16, that is, at 9.29 a.m. on January 17 local standard time, when the sun would be well above the horizon. The measures were continued until January 17, 0h. 8·6m. (Johannesburg M.T.), that is, midday, and they showed that the comet was rapidly approaching the sun, the apparent movement per hour being +42s. in R.A. and +6·5′ in declination.

Mr. Innes described the comet as having a head 5′ in diameter, and a well-developed tail; in a later message the latter was stated to be 1° long, fan-shaped, and visible to the naked eye. This observation emphasises the exceptional brilliance of the comet and the purity of the Transvaal atmosphere, for at the time of observation the comet was within 4½° of the sun and west of it.

The apparent motion was so rapid that by the time the discovery was announced here the comet had passed to the east of the sun, and was therefore to be seen at or after sunset instead of before or at sunrise. The Cambridge Observatory appears to have been the most fortunately situated of English observatories, for the sky was clear enough on January 19 to warrant an attack in force, and Mr. Hubrecht was, according to Saturday's *Daily Mail*, fortunate enough to find the comet straight away. Mr. Hinks thereupon secured a measure of the position, and saw a nucleus as bright as Mercury, and a tail 2° long; on Thursday, January 20, the nucleus was seen to be brighter and the tail further developed.

According to a Central News correspondent, the comet was seen, in full daylight, at the Milan Observatory, but no tail was seen. The observations of the tail vary considerably in their estimates of its length, but this is to be expected, for, obviously, the prominence of such a filmy structure in daylight or twilight will vary greatly with the purity of the atmosphere.

At Oxford, Prof. Turner found the comet quite a conspicuous object, in field-glasses, at 5 p.m. on January 20, and could see it quite easily with the naked eye; he made his observations from the Robinson Tower of New College.

On Friday, January 21, the Cambridge observers were again favoured, and, according to the *Times*, Mr. Hinks found the comet to be considerably brighter than on the preceding day, and to have a fine stellar nucleus with the surrounding envelopes well developed. Prof. Dyson, at the Royal Observatory, Edinburgh, also saw the nucleus. The same day, Mr. J. H. Elgie, observing at Leeds, saw the comet at 5 p.m., and describes it as "weirdly magnificent," having a tail 8° long. The nucleus, he estimated, was as bright as Mars at the recent opposition, and the tail was curved, with the concave side towards Venus; the outer edge was then well defined, but further observations, on Saturday, showed it to be much more diffused. The Rev. F. J. Jervis-Smith, writing from Lymington, says that several persons observing there on January 22 thought the tail appeared to flash slightly and continuously, but this phenomenon may have been due to the low position of the object and consequent atmospheric effects.

The lengthy reports in Monday's *Times, Daily Mail, Chronicle*, &c., show that the comet was well observed during the week-end. On Saturday, January 22, Prof. Turner secured two photographs showing the brighter portions of the tail, and four photographs were taken at the Dunsink Observatory. Dr. Whittaker and his assistants at Dunsink also observed the comet visually, and found that, in addition to the tail, extending upwards to a distance of 8°, where it was lost in a dense cloud, there was a distinct jet, or horn, of light on that side of the head nearest to the horizon. The head of the comet appeared as a dusky-red nucleus surrounded by a nebulous envelope of fainter red, and was as large as, or larger than, Mars. The twin tails were of a bright yellow colour.

Dr. Rambaut observed the comet with the 10-inch and 18-inch telescopes at the Radcliffe Observatory on January 22, and saw it quite well, despite a thick haze. Prof. Dyson also made observations at Edinburgh, and found, at 5.25 p.m., that the head was as bright as Mars and had a nucleus 45″ in diameter, whilst the tail extended to a distance of 7°. At Cambridge it was estimated to be 6° long. The orbit computed by Messrs. Stratton and Hubrecht, at Cambridge, shows that the comet passed through perihelion on January 17, at a distance of two million miles from the sun, and will continue to move northwards with diminishing speed.

At the Solar Physics Observatory, South Kensington, and, we understand, at the Royal Observatory, Greenwich, the careful preparations for observing, and the constant attendance of the staff during the hours available for observations, were, until Tuesday evening, rendered nugatory by clouds, or by the persistent smoky haze which, even on Saturday, rendered Venus a faint object, and made quite hopeless the careful search for the comet. But on Tuesday evening observations were secured by Dr. W. J. S. Lockyer, using the 10-inch refractor, and these showed that, at 5.35 p.m., the Kiel position was in error to a slight extent in R.A. and about 2° in declination, the observed place being further south than that indicated by the ephemeris.

In a telegram transmitted by Prof. Pickering to the

Astronomische Nachrichten (supp. No. 4383) it is announced that Dr. Wright, of the Lick Observatory, has made a daylight observation which shows the spectrum of the comet's nucleus to be continuous, with the sodium, D, lines bright. Similar observations are reported in the *Daily Telegraph* (January 24) from the Glasgow Observatory, with the addition of a "hydrocarbon" band. This occurrence of the D lines recalls the Wells's, and the Great, comets of 1882, in which Copeland and Lohse observed the same lines intensely bright, due, according to Copeland, to the near approach of the comet to the sun. In the present case the rapidity with which the comet appears to have travelled when near perihelion further suggests a similarity.

The publication of a set of elements and an ephemeris by the Kiel Centralstelle (Circular No. 117) provides for observations during the next few days. The elements are based on observations made at Algiers on January 18, 19, and 20, and are as follows:—

Elements.

$$T = 1910, \text{ January } 17{\cdot}42 \text{ (M.T. Berlin).}$$

$$\left.\begin{aligned}\omega &= 263^\circ\ \ 5{\cdot}7'\\ \Omega &= \ \ 8^\circ\ 56{\cdot}2'\\ i &= \ 62^\circ\ 10{\cdot}1'\end{aligned}\right\} 1910{\cdot}0$$

$$\log q = 8{\cdot}6169$$

The following is an abstract from the ephemeris:—

Ephemeris for oh. (M.T. Berlin).

1910		R.A. h. m.		Decl. ° ′
January 26	...	21 25·3	...	+0 20
27	...	21 31·2	...	+2 30
28	...	21 36·7	...	+4 14
29	...	21 42·1	...	+6 2
30	...	21 47·2	...	+7 45

Observations made by Prof. Turner, Dr. Lockyer, and others, indicate that this ephemeris is incorrect in declination, and that on January 25 the observed position was about 2° south of that given by the ephemeris. Prof. Turner reports that the discordance is increasing.

Observations made on January 24 and 25 indicate that the comet's brightness is decreasing. In the *Times* of January 25, Sir Robert Ball reported that "Prof. Newall finds a remarkable spectrum," and the Rev. T. E. R. Phillips stated that the double tail was not unlike that of the great comet of 1874, but with the gap in the centre much wider than in that case. Further photographs were secured at Dunsink and Oxford on Tuesday. In the *Times* of January 26 Sir Robert Ball reports that the comet was again observed, between 5 and 6 p.m. on Tuesday. It was much fainter than on Saturday, but the tail was quite 10° long, and was slightly curved towards Venus. The bright yellow light was still present, but fainter.

Bright, "daylight," comets are not frequent visitors; the tale for the nineteenth century is practically completed by the comets of 1843, 1847, 1853, 1861, and 1882, and it is a curious coincidence that this present visitor should arrive at the time when we had settled down to the carefully ordered study of the rediscovered Halley. But reference to the notes presented to the Royal Astronomical Society by Messrs. Cowell and Crommelin will show that the coincidence is not unique; quite a number of returns of Halley's comet have been marked by the appearance of exceptionally bright sporadic visitors.

The present object has been introduced to us under a misnomer. The *Astronomische Nachrichten* now tells us that the appellation "Drake" is simply due to a misinterpretation of "great" as the message was being transmitted by telephone; popularly it is the "Daylight Comet."

W. E. ROLSTON.

NOTES.

WE regret to see the announcement of the death, at Marburg, of Prof. F. Kohlrausch, the distinguished physicist, at seventy years of age.

THE death is announced, at sixty-two years of age, of Prof. H. Brunner, professor of toxicological chemistry in the University of Lausanne since 1876.

THE Friday evening discourse at the Royal Institution on February 4 will be delivered by Prof. W. Bateson, F.R.S., on "The Heredity of Sex."

PROF. A. LACROIX has been elected president for 1910 of the Geological Society of France. M. Œhlert, Mme. Œhlert, Prof. Vidal, and M. Cossmann have been elected vice-presidents. This is the first time a lady has been elected to office in the society.

To the *Field* of January 22 Mr. Lydekker contributes an account of an apparently new race of buffalo obtained by Mr. Hilton-Simpson in the extreme south of French Congoland; the race appears to be allied to the red Congo buffalo, but is of much darker colour.

ACCORDING to a statement in the *Times* of January 17, three skeletons of sauropod dinosaurs have recently been discovered in the Jurassic strata of Utah by a collector from the Carnegie Museum, Pittsburg. One of the three is stated to be higher and more massive than that of the type of *Diplodocus carnegiei*, although its length—84 feet —is somewhat less.

THE council of the Royal Geographical Society has decided to award a special gold medal to Commander Peary for his journey to the North Pole, and for having undertaken such scientific investigations as his opportunities permitted; and a silver replica to Captain Bartlett for attaining eighty-eight degrees north latitude.

ACCORDING to the New York correspondent of the *Times*, the U.S. Department of Commerce and Labour has under consideration the dispatch of the Government steamship *Albatross* on an expedition to the Antarctic Ocean. The expedition is the suggestion of Dr. H. F. Osborn, of the American Museum of Natural History, New York. The objects of the proposed expedition are stated to be partly commercial and partly scientific. There appears to be reason to believe that some of the remote southern islands are the homes of herds of the southern fur seal, and it is hoped to discover these, as well as to study south polar fauna generally.

A SERIES of lectures in connection with the Selborne Society has been arranged, and will be held in the theatre of the Civil Service Commission, Burlington Gardens, London, W. The first lecture of the course was delivered by Mr. F. Enoch on January 21, and dealt with insects through the camera. There was a large audience. The lecture, which aroused great enthusiasm, gave the results of many years of patient outdoor research, and was illustrated by a unique series of three-colour photographs. On February 11 Mr. W. Bickerton will lecture on wild birds and their ways; on March 11, Mr. W. M. Webb on clothes a human nature-study; and, on April 8, Miss Gertrude Bacon on wind, wave, and cloud. Fuller particulars may be obtained from the honorary general secretary of the society, 42 Bloomsbury Square, London, W.C.

IT is with regret that we see the announcement of the unexpected death of Dr. W. Page-May, fellow and lecturer of University College, London, which occurred quite suddenly at Brighton on Wednesday, January 19. To those associated with him at University College, where, during the years since his return from Helwan, he carried out his work on the central nervous system, as well as to a far larger circle of friends, his early death, when he was in the full vigour of his intellect, has been felt as a heavy loss. Dr. Page-May brought a well-trained mind to the study of neurology. He was thoroughly familiar with the literature of this subject, and also with all the special physiological and histological methods which have so largely contributed to those conceptions, which are held at the present time, of the minute structure and modes of action of the brain. Several researches were in actual progress at the time of his death. Among the more important of his papers we may mention the "Investigations into Segmental Representation of Movements in the Lumbar Region of the Mammalian Spinal Cord," published in the Philosophical Transactions of the Royal Society, 1897; and numerous papers in *Brain*, on "The Afferent Path," and, in collaboration with Dr. Gordon Holmes, "On the Exact Origin of the Pyramidal Tracts in Man and other Mammals."

Records of severe earthquake shocks were obtained at many seismological observatories on Saturday, January 22. The following observations of shocks are recorded:—at 7.45 a.m. at Seydisfjord, in Iceland; at Akureyri, in the same island, at about 8 a.m.; at 8.52 a.m. by Prof. Milne at Shide, in the Isle of Wight; at 8.45 a.m. by Prof. Belar at Laibach, in Austria. A disturbance was registered at the Parc Saint-Maur earthquake station, Paris, at 9 a.m., and was most violent from 9.4 to 9.24 a.m. The French observers locate the earthquake as occurring at a distance of about 3000 kilometres from Paris in a south-easterly direction, and it is believed to have visited the Caucasus or Armenia. Prof. Milne is reported to have estimated the distance of the origin of the shock at a little more than a thousand miles. Prof. Belar is said to have given the distance as 2500 miles, and suggests Asia as the seat of the disturbance.

The council of the Royal Meteorological Society has forwarded a memorial to the Royal Commission which is now inquiring into the work of the University of London urging that the time is fully ripe for placing the study of meteorology on a more satisfactory basis, and for its inclusion among the subjects for degree examinations. The council has arranged for a provincial meeting to be held at Manchester on February 23, and it is hoped that this will be the means of making the work of the society better known in a district in which considerable attention is already being given to meteorology. At the annual meeting of the society the president presented to Dr. W. N. Shaw, F.R.S., the Symons gold medal for 1910, which had been awarded to him in consideration of his distinguished work in connection with meteorological science.

Mr. Edward T. Connold, whose death is announced, was born at Hastings on June 11, 1862. He is best known from his researches in connection with British plant-galls, upon which he published the following beautifully illustrated works:—"British Vegetable Galls" (1901), "British Oak Galls" (1908), and "Plant Galls of Great Britain" (1909). At the time of his death he had in preparation a work on British wild fruits. His collection of plant-galls is exhibited at the Hastings Museum, in which institution he took great interest. On the formation of the Hastings and St. Leonards Natural History Society in 1893 he became honorary secretary, and at once entered upon his duties with characteristic enthusiasm. He was an excellent lecturer on popular natural history, while his skill as a photographer is attested by the plates with which his published works are embellished.

We have to acknowledge the receipt of a catalogue of publications relating to "Evertebrata," issued by Mr. W. Junk, of Berlin, and containing more than six thousand items.

Dr. C. Hosseus, of Berlin, communicates to the January issue of *Urania* a brief *résumé* of two collecting trips in Siam, in the course of which much valuable material was obtained. Special attention is directed to the important *rôle* played in Siam by elephants, which, unlike their cousins in India, breed more or less freely in captivity.

Naturen for January opens with a long and well-illustrated article, by Dr. D. Damas, on the oceanography of Greenland, based on the observations made by the *Belgica* expedition of 1905. Maps show the extent of the ice at different seasons, while the bathymetrical variation in salinity is illustrated by diagrams.

In the January number of *Knowledge* the question is raised, under the heading "Zoological Notes," whether there were ever English species-names for many of the better known kinds of animals, the two sexes of which have distinctive designations of their own. As examples may be cited mallard and duck, bull and cow, dog and bitch, and horse and mare. In the opinion of the writer of the note, no species-name originally existed in these and many other cases.

In the Journal of the Quekett Microscopical Club for November, 1909, Mr. W. Wesché states that, having discovered a few years ago the viviparous propagation of the tachinid fly known as *Phorodera serriventris*, he was at a loss to understand why the female required an ovipositor, more especially one of unusual form. The problem was solved by observations made at Mersea Island, off the Essex coast, last summer. From these it appears that, after birth, the living larvæ are introduced by means of a very sharp hook on the under surface of the body of the female into the bodies of caterpillars, the fly making an aperture for their entrance by forcing the hook into its victims. The necessary purchase on the body of the caterpillar is obtained by the grip of the two serrated abdominal plates in advance of the hook, this giving a hold in an opposite direction to the force expended on the penetrating hook. When not in use, the hook is folded in the median line under the abdomen. The larvæ have strong chitinous jaws, which are visible through the integuments of the gravid female, and in one instance the author counted no fewer than ninety-eight jaws, although such a number appears to be unusual.

The greater portion of the contents of vol. xxxi., Nos. 3 and 4, of Notes from the Leyden Museum, is devoted to entomological subjects, among which reference may be made to a paper, by Dr. A. Forel, on ants obtained on Krakatau and in Java by Mr. E. Jacobson, with biological notes by the collector. The latter gives copious notes on the habits of the species known as *Polyrhachis dives*, of which a colony was in the habit of invading the bathroom of his residence. The ants effected an entrance through a chink in the wall, so that the nest could not be discovered. They made their appearance in the evening, but were in no wise disconcerted by gaslight, and so freely did they drink that their abdomens became greatly distended. The author, who kept many of these ants in captivity, gives figures of three of their nests. In July, 1905, he found that many of the ants were badly infested with nematode worms, the stomach of one in dividual containing no fewer than fifteen parasites. A nematode taken by Mr. Jacobson from *Camponotus maculatus* was described by Dr. von Linstow as a new species, under the name of *Ochetocephalus javanicus*, in vol. xxix. of the "Notes."

Prof. G. Haberlandt has arranged with the publishers of his "Physiologische Pflanzenanatomie" to issue separately the chapters from the latest edition of his book dealing with the perceptive organs of plants. This gives botanists the opportunity of obtaining in a small brochure, at a price of two marks, the essence of the experiments and arguments put forward by the author and other physiologists in connection with the statolith theory of gravity-perception, and in favour of regarding such anatomical peculiarities as papillæ, hairs, &c., in certain plants as mechanisms for the perception of light and contact.

Individual variation in the development of plants is the subject of a paper, by Dr. K. Koriba, forming vol. xxiii., art. 3, of the Journal of the College of Science, Tokyo. Horse beans and peas were germinated and afterwards grown, some as water-cultures in tap-water, others in solutions containing zinc or copper sulphate, and others again in soil. Their development was estimated chiefly by the increase of length in stem and root. It is noted that these organs respond differently to changes in external conditions. Thus growth of the root continues at a lower temperature than growth of the stem, while at a higher temperature the reverse holds good; also a poisonous solution affects the root more readily. According to the observations quoted, heavy seeds do not always germinate most quickly, so that individual quality is considered to be more potent than weight.

The report for the year 1908 of the director of the botanic gardens and Government domains in Sydney has been received. There is special reference among native plants to a new variety of the shrub *Acacia salina* and the monocotyledonous plant *Aneilema gramineum*, related to Tradescantia. A number of the latest successful introductions come from South Africa, notably species of Aloe; these and species of Agave from Mexico appear to find the climatic conditions they require. Among the grasses, *Festuca arundinacea* and *Panicum muticum* are regarded as valuable species alike for fodder purposes and for decoration. A list of troublesome weeds includes *Allium fragrans*, *Cyperus rotundus*, *Hypochaeris radicata*, *Medicago denticulata*, and *Portulaca oleracea*.

A sketch of the flora of Siam is contributed by Dr. C. C. Hosseus to *Globus* (vol. xcvi., Nos. 10 and 11), where he describes the chief types of vegetation studied by him during several journeys into the interior. The country is rich in forests. An extension of the Indian sub-Himalayan pine forests, where *Pinus Khasya* is dominant, is found in the extreme north. There are luxurious evergreen forests containing oaks, laurels, species of Cinnamomum, Cephalotaxus, and Podocarpus at different altitudes, where lianes, ferns, and orchids grow in profusion. The teak forests seldom rise above 900 feet; the predominating teak is accompanied by *Albizzia procera*, *Butea frondosa*, and Xylia. The Dipterocarp forests growing on laterite also show a great wealth of vegetation. Below these formations occur the forests and grass lands of the Savannahs, while near the coasts the swamps provide habitats for Pistia, Salvinia, Azolla, Nymphæa, and Nelumbium. Finally, a mangrove belt lines the islands and coasts.

The North Carolina Department of Agriculture has issued an illustrated bulletin on some common birds of the farm, including the *bob-white* (*Colinus virginianus*), night-hawk or "bullbat" (*Chordeiles virginianus*), meadow-lark (*Sturnella magna*), and the various wood-peckers. Particular attention is directed to the food they take.

The first of the new series of scientific bulletins issued by the University of Wisconsin Experiment Station deals with the function of phosphates in the nutrition of animals. At least 3 grams of phosphorus were found to be necessary for a growing pig of 50 lb. weight, otherwise the animal withdrew from its skeleton both calcium and phosphorus in the proportions found in tri-calcic phosphate. In another bulletin, dealing with the phosphate contents of soils, we find the remarkable result that heavy manuring such as is practised in tobacco culture led to a great loss of phosphates from the soil. N/5 nitric acid proved a useful solvent in determining whether or not soils are deficient in phosphates.

The Proceedings of the Indiana Academy of Science contain reports of the papers read at the twenty-fourth annual meeting at Purdue University, Lafayette, Indiana. The president, Mr. Glen Culbertson, dealt with deforestation and its effects among the hills of southern Indiana. A report was also presented on the work of the pathological laboratory of the Central Indiana Hospital for the Insane, Indianopolis. Other papers dealt with local mycological problems, heterœcious plant rusts of Indiana, the rust of timothy, dissemination of disease by means of the seed of the host plant, and so on. There is an anthropological paper on the "shake" dance of the Quilente Indians, and a number of chemical and biological papers.

Attempts have been made to introduce into the West Indies from the United States new varieties of ground nuts, noted for the large size of the nuts and their heavy yield. The results have been somewhat disappointing, partly on account of the severe attacks of fungi. A description is given in a recent issue of the *Agricultural News* of the fungi already observed, but there are others still to be identified. One of the Uromyces has done a good deal of damage, and could not be kept in check by the ordinary remedies. Another fungus, not yet identified, attacks the roots. The diseased portions exhibit a fine web-like mycelium, covered in its older portions with straight, rod-like crystals. These form small white tufts, which grow somewhat, become yellow, and finally brown. They are about a quarter of an inch in diameter when fully grown, and roughly spherical in shape. In fruiting they show two or three layers of firm, brown hyphæ forming an outer covering which encloses a mass of swollen colourless hyphæ, complete but undifferentiated. They are probably of the nature of sclerotia. No other fruiting bodies have yet been found.

The Journal of the College of Agriculture, Tohoku Imperial University, Sapporo, Japan, contains a paper by S. Ito (in English) on the Uredineæ parasitic on the Japanese Gramineæ. Some 800 specimens were examined, collected from different parts of Japan, from Saghalien and the Kurile Islands in the north to Formosa in the south. They fall into six genera. Seventy-three species and two varieties are recorded for the first time in Japan, while no fewer than twenty-one are altogether new to science. The other paper, by Y. Niisima, contains a detailed description (in German) of the Scolytidæ injurious to forest trees. There is an enormous mass of detail in these papers, and the illustrations are very beautifully done; indeed, the publications of the Japanese agricultural colleges are beyond question the most beautifully illustrated of the agricultural journals.

THE current West Indian Bulletin (vol. x., No. 2) contains, as usual, a number of interesting articles on West Indian products. Among them is a statement of the present position of the cotton industry, showing a rapid increase in spite of one or two set-backs in a few unsuitable districts. The estimated value of the lint in 1902 was 7366*l.*; in 1907 it was 172,294*l.* A pamphlet is also issued summarising the experiments on sugar-cane at Barbadoes with seedling canes and with various manures. The striking result was brought out that potash and nitrogen manures increased the amount of sugar while phosphates diminished it. The Bulletin of the Jamaica Department of Agriculture, the second of the new series, is quite up to the standard set by the first, and contains an interesting article, by Mr. Ashby, describing the bacterial production of sulphuretted hydrogen from certain obnoxious ponds near Jamaica. There are also some well illustrated and interesting articles on the Indian cattle of the island and the Hereford herd of Knockalva.

AN interesting preliminary notice, by Mr. P. A. Curry, of the results obtained in the research of the upper air above the Blue Hill area during the rainy season of 1909 is published in the *Cairo Scientific Journal* for October last. The main object was to find the direction and velocity of the wind at different heights above Roseires by the use of small pilot balloons, of which seventy-nine were released. The surface wind, which was slightly west of south, veered to south-west at 1500 metres; at 3000 m. north-east winds were somewhat predominant, veering to slightly north of east at 3500 m. From that altitude to 6000 m. it was very constant in direction, at which point it backed slightly to north-east at 9000 m., then veering again to east at 12,000 m. One balloon which rose above this showed a due east wind at 13,000 m. and 14,000 m., veering to east-south-east at 18,000 m. Up to 3000 m. the velocity averaged little more than 5 metres per second, increasing to 10 m.p.s. at 6000 m.; it then decreased to 8 m.p.s. at 7000 m., and remained fairly steady up to 10,000 m. Above this altitude the velocity increased rapidly. The results show a fairly steady circulation whether rain falls or not, and the limiting height of the upper easterly drift does not decrease on dry days, as was found to be the case in Abyssinia.

DR. G. H. SAVAGE has sent us a reprint of the Harveian oration delivered by him before the Royal College of Physicians of London on October 18, 1909. Dr. Savage selects for the themes of his lecture experimental psychology and hypnotism, and emphasises the importance of taking into consideration the teaching and methods of these subjects with regard to neurological and mental pathology.

MR. B. A. GUPTE, assistant director of ethnography for India, has issued the preliminary draft of a collection of passages from the sacred books of the Hindus, Jains, Buddhists, and Mohammedans, dealing with women in India, their life, morals, character, rites, and ceremonies, which is of considerable interest. In a subsequent edition the compiler would do well to give definite references to his authorities, which would add considerably to the interest of the collection.

IN an article entitled "Mental Processes and Concomitant Galvanometric Changes" (*Psychological Review*, January), Dr. Daniel Starch investigates the changes in resistance of the body to a weak electric current during varying mental conditions. He concludes that all kinds of mental states are accompanied by galvanometric changes, and that emotional states and muscular activity produce the widest deflections, habitual activity and the process of visual attention producing the least. He finds that quiet mental activity, even when considerable effect is involved, produces only small galvanometric effects.

IN a note published in the Bulletin of the Imperial Earthquake Investigation Committee (vol. iii., No. 2, Tokyo) Prof. Omori considers briefly a subject already touched on by Mr. Oldham, namely, the dependence of the velocity of seismic waves on the nature of the path traversed by them. He calculates the mean surface velocity of the first preliminary tremors by the "difference method" for three earthquakes, and finds it to be 16·02 km. per second for the Guatemala earthquake of 1902, 11·36 km. per second for the Indian (Kangra) earthquake of 1905, and 13·97 km. per second for the San Francisco earthquake of 1906. In the first case the wave-paths were mainly submarine, in the second mainly continental, in the third partly continental and partly submarine. The differences in velocity may thus be due to a deficiency in rigidity in the continental portions of the crust (especially in the centre of Asia) and to an excess of rigidity beneath the Pacific and Atlantic Oceans.

THE Mines Department of South Australia has issued an interesting report, dealing with the mineral output of the State for the half-year ending June 13, 1909 ("A Review of Mining Operations in the State of South Australia during the Half-year ending June 30, 1909," No. 10, Adelaide, 1909). The chief mineral in South Australia is copper, produced from a large number of small scattered mines, but they were less active than usual owing to the low price of copper. There are many small gold mines, of which Arltunga is the most important field, but, owing to its inaccessible position, only very high-grade ores can be worked there. The average grade of the ore in the thirty small mines reported is 102*s.* per ton. The total quantity of ore treated from this field has been only 10,000 tons. Steady progress is being made with the phosphate mines, and a company is working one of the numerous deposits of high-quality china-clay found in South Australia.

IN the *Electrician* for January 7 Mr. Fournier D'Albe commences a series of articles on recent advances in electrical theory. The first instalment deals with the doubts which have been recently cast on the necessity for assuming an æther, with the principle of relativity, the Fitzgerald-Lorentz theory of the change of length of a body moving through space, and with the problem of aberration. The articles should prove a useful introduction to a subject which is one of the most interesting before the scientific world at the present time. There is a slight error in the statement of the amount of expansion of a rod which observers would postulate if the observed times of to and fro motion of light were the same with the rod at rest and in motion through the æther parallel to its length respectively. The amount of change stated by the author is that which would be postulated if the times were found the same when the rod moved with the same velocity with respect to the æther parallel and perpendicular to itself respectively, as in Michelson and Morley's experiments.

IN the December (1909) number of *Le Radium* M. Jean Perrin gives an account of his measurements of the Brownian movements in emulsions of gamboge and of mastic, and of the calculations of a number of molecular constants he has based on those observations. If it is assumed that the movements of the granules in such emulsions can be classed with those of the molecules of a gas, the theory of the equal partition of the energy amongst the molecules of mixed gases leads to the conclusion that the mean kinetic energy of translation of these granules is identical with that of gas molecules. If, then, the kinetic energy of the granules can be determined, the number of gas molecules in a cubic centimetre of gas under normal conditions may be calculated. M. Perrin determines the kinetic energy of the granules in two independent ways:—first, from measurements of the distribution of the granules at different heights in the emulsion, which he finds follows the same law as in gases; second, from measurements of the displacements of the granules in a given time, and the law which Einstein has deduced for the connection between displacement and mean kinetic energy. Both lead to the conclusion that the number of molecules in a gram molecule is $70{\cdot}5 \times 10^{22}$.

COMMENTING on the death of M. Delagrange, *Engineering* for January 14 points out two special features of technical interest in this aëroplane accident. In the first place it is the first fatal accident with a machine of the monoplane type, and, in the second, it is the first which appears to be distinctly owing to a failure in the main structure of the machine used. It seems to have been generally assumed that the biplane is a safer machine than the monoplane, yet the fact remains that the greater number of accidents have happened to the biplane. There seems to be good reason to suppose that the death of M. Delagrange was caused by the main framing forming one of the wings giving way altogether, followed by the fall of the machine. The general construction of the framing is that of a trussed girder constructed of wood and steel wire. The wires are very numerous in the biplane as compared with those required in the monoplane frame. Usually the wire stays are of solid steel wire or ribbon, which gives little indication of readiness to break. Stranded wire rope is better from this point of view, as ample warning is always given by some of the strands breaking before the rope finally gives way. The broken strands are very easily detected. Further, many machines of both types have the spars insufficiently stayed or not stayed at all against the longitudinal pressure due to the air resistance, which pressure in such cases will be taken up entirely by the spars. To make the aëroplane of practical use, trustworthiness and safety are required, and more attention should be given to these rather than to cutting down structural weights for the purpose of striving after "records."

THE December (1909) number of the *Journal of Physical Chemistry* contains a series of determinations, by Messrs. O. C. Schaefer and H. Schlundt, of the dielectric constants of the anhydrous halogen acids, which gave the following values:—

HI	21·7°, 2·90; −50°, 2·88; −70° (solid), 3·95.
HBr	24·7°, 3·82; −80°, 6·29.
HCl	27·7°. 4·60; −90°, 8·85.
HCN ...	−25° (solid), 2·4; −70° (solid), 3·05.

Attention may also be directed to a paper, by Mr. M. M. Garver, on a kinetic interpretation of osmotic pressure, in which the fundamental assumption is made that, whilst the average velocity of water-molecules in a sugar solution is the same as in pure water at the same temperature, the *range of variation* on either side of the mean is greatly reduced, so that vaporisation and freezing are alike rendered more difficult.

THE volume of the Journal of the American Chemical Society, which has just been completed, is remarkable, not only for the importance of the researches that are described in it, but also for the excellent conciseness with which the results are presented. Two papers by Mr. F. F. Rupert, on the properties of aqueous ammonia and aqueous hydrochloric acid, might be cited as models, not only of accurate and thorough investigation, but of successful resistance to the temptation to expand the bulk of the paper in proportion (or out of proportion, as the case may be) to the importance of the subject. The isolation of ammonium hydroxide, $(NH_4)OH$, and of ammonium oxide, $(NH_4)_2O$, is recorded, for instance, in a paper which covers less than three pages, and congratulations are due from the reader to authors and editor alike on the excellent results that have followed from their cooperation in this respect. The contents of the volume are of such a character as to give much support to the invitation that has recently been extended to English chemists to become members of the American society.

THE Institute of Chemistry has issued a third edition, revised and enlarged, of the "List of Official Chemical Appointments." The list has been compiled by Mr. R. B. Pilcher, registrar and secretary of the institute, and is sold at 2s. net. It is arranged in three main divisions:—appointments in Great Britain and Ireland, under the various departments of State, county and borough councils, and other authorities, together with professorial and teaching appointments in schools and colleges in this country; appointments in India and the colonies; and an appendix giving information regarding chemical societies and institutions. A register of fellows and associates of the institute who are seeking appointments is kept at the office of the institute, so that authorities may obtain the services of qualified professional chemists as vacancies arise. In many instances particulars are given in the list as to the Acts of Parliament under which appointments are made, and the regulations and conditions governing the selection of candidates for them. Intended primarily for the use of professional chemists, the publication should be found useful by authorities and persons interested in the applications of chemistry to purposes of State and in the promotion of higher chemical instruction.

A SECOND edition of Mr. G. M. Norman's "Systematic Practical Organic Chemistry" has been published by Mr. W. B. Clive at the University Tutorial Press, Ltd. Various alterations and additions have been made to the book in order to meet the new requirements of the Board of Education syllabus in the subject.

THE popular lectures to be given at the Royal Victoria Hall, Waterloo Bridge Road, S.E., on Tuesdays during February, include the following:—Mr. H. S. Rowell, on "Aëronautics"; Mr. Horace W. Monckton, on "Berkshire, Geological, Geographical, and Historical"; and Mr. E. Cuthbertson, on "The Constitution of Atoms."

COTTERILL AND SLADE'S well-known text-book, "Lessons in Applied Mechanics," has now been published by Messrs. Macmillan and Co., Ltd., in two parts. The first volume includes the sections dealing with the principle of work and hydraulics, and the second those concerned with the strength of materials and structures. The separate volumes meet the needs of students preparing for the various examinations in applied mechanics held by the Board of Education.

OUR ASTRONOMICAL COLUMN.

HALLEY'S COMET, 1909*c*.—A further extract from Mr. Crommelin's corrected ephemeris (*Astronomische Nachrichten*, No. 4379, p. 170) for Halley's comet is given below:—

Ephemeris for Greenwich Noon.

1910	R.A. h. m.	Decl.	log *r*	log Δ
Jan. 30	1 6·4	+ 8 27	—	0·2284
Feb. 4	0 59·1	+ 8 14	0·1916	0·2410
9	0 52·8	+ 8 4	—	0·2522
14	0 47·6	+ 7 58	0·1473	0·2617
19	0 42 6	+ 7 55	—	0·2688
24	0 38·1	+ 7 54	0·0971	0·2743
Mar. 1	0 34·0	+ 7 55	—	0·2774

These positions will be found plotted on the chart which we gave in our issue for January 13, p. 320, and it will be seen that the comet is now apparently travelling slowly westwards through the constellation Pisces; on February 5 it will be nearly 1° north of the 4·5 magnitude star ε Piscium. During February the comet's distance from the sun will decrease from about 151 to 108·7 million miles, whilst the distance from the earth will increase from about 157 to 176 million miles. According to the ephemeris given by Prof. Searle in No. 607 of the *Astronomical Journal*, the brightness should, during February, increase from 20 to 30, the unit taken being the brightness on September 11 when re-discovered. In the same journal Prof. Barnard gives some further observations, and states that on December 7 the comet was an easy object, appearing to have a small nucleus, in the 4-inch finder of the 40-inch telescope. In the latter it appeared much larger, and its magnitude was about 10·5.

In No. 4383 of the *Astronomische Nachrichten* (p. 238) Herr Archenhold describes the occultation of a twelfth-magnitude star by the nucleus of the comet on December 5, and, among other things, records that no appreciable change of the colour of the star was caused by the superposition of the comet; the nucleus was sharply defined, and by Argelander's method Herr Archenhold found that its magnitude was 11·8.

OTHER PERIODIC COMETS DUE TO RETURN THIS YEAR.—In addition to Tempel's second, and D'Arrest's comets, five other periodic comets may be picked up during 1910, and notes concerning them are given in No. 1, vol. xviii., of *Popular Astronomy* (January, p. 47).

Giacobini's comet, 1896 v., passed perihelion in December, 1909, according to the latest calculations, and its detection now is unlikely. Swift's comet, 1895 ii., is due at perihelion during the present month, but is unfavourably placed. Spitaler's comet, 1890 vii., is, according to the recent calculations of Dr. Hopfer (*Astronomische Nachrichten*, No. 4371), likely to pass perihelion early in October, and might, had a search been made, have been recovered in 1903; between 1897 and 1903 this comet suffered considerable perturbations by Jupiter, which lengthened its period from 6·42 to 6·82 years. Faye's comet is due at perihelion, in very favourable circumstances, in the latter part of October, and Brooks's comet, 1889 v., is more likely to be seen during the summer of 1910 than when near perihelion in January, 1911.

WINNECKE'S COMET.—In No. 4383 of the *Astronomische Nachrichten* Dr. Perrine states that Winnecke's comet will soon be too faint for him to follow with the 12-inch refractor at Cordoba. As it is moving northwards rapidly, he suggests that further observations may be secured with the larger instruments of the northern hemisphere. Dr. Hillebrand's ephemeris for this object appeared in No. 4374 of the *Astronomische Nachrichten*, and Dr. Perrine states that observations made on 1909 December 10 gave a correction (Obs.-Eph.) of R.A., −55s.; dec., 0′.

THE EPOCH OF THE LAST SUN-SPOT MAXIMUM.—In No. 12, vol. xxxviii., of the *Memorie della Società degli Spettroscopisti Italiani*, Dr. Wolfer discusses the epoch of the most recent sun-spot maximum. The observations show that the spot activity was maintained from 1905 to 1908, but, as there was a marked diminution in the latter year, continued in 1909, he concludes that the maximum is passed, and proceeds to determine its epoch. This is not a simple matter, because there were three marked waves, reaching their maxima in November, 1905, July, 1906, and February, 1907, respectively, and three smaller ones; in this respect the maximum strongly resembles that of 1829 and, less so, that of 1804. However, from the relative numbers Dr. Wolfer obtains 1906·1 as the principal maximum, and from the same data, compensated, 1906·4. This gives the interval from the preceding maximum as 12·3 years, 1·2 years in excess of the mean period 11·1 years. With regard to the intensity of the maximum, Dr. Wolfer finds that 1906·4 follows those of 1884 and 1894, making the third maximum of feeble intensity, and he discusses the observations made since 1750, showing that periods of great and small maxima follow alternately.

"ANNUARIO" FOR 1910 OF THE MADRID OBSERVATORY.—The annual publication of the Madrid Observatory is a substantial volume of 560 cap. octavo pages, and contains, *inter alia*, the usual calendars and astronomical tables, a dissertation on the nature, distances, motions, &c., of stars, and a *résumé* of the solar observations made at the observatory during 1908. The prominence observations are tabulated in detail, and then summarised in the form employed by Prof. Ricco. Meteorological results are also given.

A STUDY OF BARK-BEETLES.

THE entomological publications of the United States Department of Agriculture have for long past been the admiration of European naturalists. Exceptionally valuable, even among that Department's series of excellent memoirs, are two recent papers on Scolytid beetles of the genus Dendroctonus by Dr. A. D. Hopkins, one (Technical Series, No. 17, part i.) being in the main systematic and descriptive, the other (Bulletin No. 83, part i.) dealing for the most part with the bionomics of the beetles and the *rôle* played by the various species as depredators in North American forests. These papers contain some of the results of seventeen years' original research; probably no such descriptions and figures of the

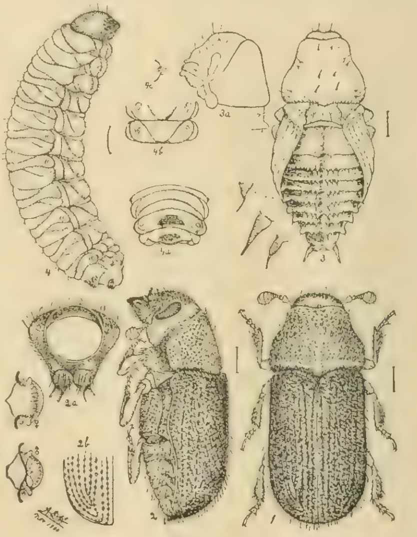

FIG. 1.—Eastern Spruce Beetle (*Dendroctonus piccaperda*). 1, Dorsal aspect; 2, lateral aspect; 2*a*, prothorax; 2*b*, end of elytron, showing sculpture; ♀, ♂, seventh abdominal terga of female and male (the clear oval spaces are stridulating areas; 3, pupa, dorsal aspect with spines more highly magnified; 3*a*, head and prothorax of pupa, lateral aspect; 4, larva, lateral aspect; 4*a*, terminal abdominal segments of larva, dorsal view; 4*b*, abdominal segments of larva, ventral view.

imaginal and larval anatomy of Scolytid beetles as those in the technical memoir have ever been issued before, while in the systematic portion are to be found, not only full structural accounts of the various species, but figures showing the characteristic form of the brood and larval galleries in each case. The accompanying figures, slightly reduced from the original, give some idea of Dr. Hopkins's excellent illustrations.

Most Scolytid beetles—the well-known *Hylurgus* (or *Myelophilus*) *piniperda*, for example—lay their eggs in dying or unhealthy trees or in felled trunks, the vigorous flow of sap and secretion of resin in healthy growing trees being unfavourable for the development of the larvæ. Members of the genus Dendroctonus, however, prefer, as a rule, healthy trees for breeding purposes; hence the destruction wrought by the insects may become exceedingly serious (see the photograph reproduced), and it is not possible to exterminate large numbers of the beetles and larvæ by "trap-trunks" or "trap-logs," according to the practice of German foresters with Hylurgus and similar bark-beetles. As is usual in American economic work, attention has been paid to the natural enemies of the destructive beetles, and experiments have been made with imported specimens of the handsome European beetle *Clerus formicarius*, which drags bark-beetles and larvæ from their burrows and ruthlessly devours them.

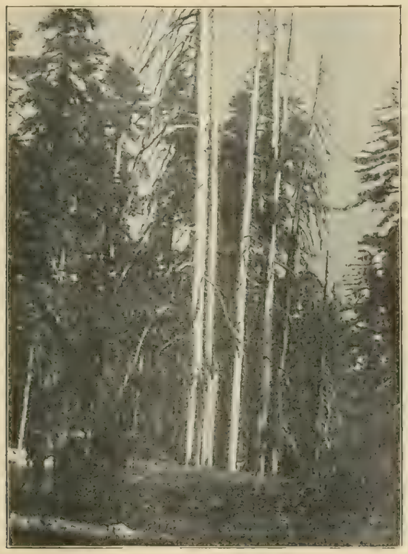

FIG. 2.—Yellow Pines killed by the Western Pine Beetle (*Dendroctonus brevicornis*), Yosemite National Park.

The genus Dendroctonus has a remarkable distribution. Twenty-three species are found in North America, the genus spreading northwards to Labrador and Alaska and southwards through the Mexican highlands into Guatemala. In the "Old World" a single species only is known—*D. micans*, which inhabits Russia, Germany, Denmark, and southern Scandinavia. While "the species of this genus of beetles are the most destructive enemies of the coniferous forest trees of North America," they are hardly known in Europe except to special students of the Scolytidæ. The absence of Dendroctonus from northern Scandinavia, from our own islands, and from western Europe generally, suggests that the former geographical connection between the outlying European *D. micans* and the numerous American members of the genus was by way of Siberia and Alaska.

G. H. C.

ATMOSPHERIC ELECTRICITY IN EGYPT.

IN Paper No. 10 of the Survey Department of Egypt Mr. H. E. Hurst discusses two years' results of atmospheric electric potential obtained from a Kelvin water-dropper electrograph at Helwan from March, 1906, to February, 1908. From observations made with a Kelvin portable electrometer, and experiments on the disturbing effect due to the presence of instrument and observer, a factor was obtained, multiplication by which transfers curve readings to potential gradient in the open (volts per metre of height). The mean value found for the potential gradient from the two years was 113, a value lower than is usually encountered in Europe. In the second year, however, owing to the more open scale employed, there was at times considerable loss of trace, and an allowance which Mr. Hurst makes for this would bring up the value of the potential gradient for that year from 119 to 129, and the mean for the two years from 113 to 118. The curves were not smoothed, and were measured only at the even hours, and there is rather excessive irregularity in the diurnal inequality curves which are given for individual months of the year. All show a prominent minimum in the early morning from 4 a.m. to 6 a.m., and some a secondary minimum in the early afternoon, but successive months differ in this respect rather widely. In the mean diurnal inequality for the year there is little variation in the potential from 10 a.m. to 10 p.m.; the value at 8 p.m. is the absolutely largest in both years. One very exceptional phenomenon is that the potential is decidedly highest in summer. The mean potential gradient from the four months June to September was 136, while that from the four months November to February was only 98, no allowance being made in either case for loss of trace. Curiously, however, the mean range of the diurnal inequality was 81 for the four mid-winter months as compared to 50 for the four months June to September.

The mean diurnal inequality for the year was analysed in a Fourier series. The amplitude of the 24-hour term was nearly double that of the 12-hour term. The latter term was found, as at Kew, to be almost exactly in phase with the 12-hour Fourier "wave" for barometric pressure. No connection could be found between potential gradient and temperature, sunshine, or any other meteorological element except wind direction and possibly vapour pressure. Other observers have associated sudden changes of potential with sunrise and sunset, but no such connection seems to exist at Helwan. During sandstorms negative potentials are sometimes encountered, but not always.

The present publication is welcome evidence of the scientific activity of the Helwan Observatory, and contains several results of much interest. It is to be hoped, however, that a more complete analysis will be made some years hence, when sufficient data have accumulated to give fairly smooth results for individual months of the year, and that the curves will then be measured at all hours of the day, and not merely at the even hours.

C. CHREE.

AMERICAN HYDROLOGY.[1]

NEGLECTING the quantity disappearing through evaporation as relatively insignificant, the rainfall over any area either finds its way on or near the surface into streams or percolates into the ground to form subterranean reservoirs, which are tapped in many cases, naturally by springs and artificially by wells. Each of these processes has a distinct and valuable bearing upon the industrial and hygienic resources of a country, and in countries where there is no separate hydrological service the scientific investigation of the national water supply comes within the purview of the geological department, as is the case in the United States. The two papers which form the subject of this brief notice illustrate in a very

---

[1] Surface Water Supply of the United States, 1907–8. Part ii., South Atlantic Coast and Eastern Gulf of Mexico. Prepared under the direction of M. O. Leighton by M. R. Hall and R. H. Bolster. Water Supply Paper No. 242. Pp. 226.

Underground Water Resources of Connecticut. By Herbert E. Gregory, with a Study of the Occurrence of Water in Crystalline Rocks, by E. E. Ellis. Water Supply Paper No. 232. Pp. 200. (Washington: Government Printing Office, 1909.)

striking manner the varied and comprehensive character of the work carried on by the U.S. Geological Survey. The first volume constitutes a general review of the surface water supply over a very considerable tract of country, comprising the drainage basins of the rivers James, Roanoke, Yadkin or Pedee, Santee, Savannah, Ogeechee, Altamaha, Satello, St. John, Peace, Withlacoochee, Suwanee, Ocklockonee, Apalachicola, Choctawhatchee, Escamba, Mobile, Pascagoula, and Pearl; while the second is a comparatively local and complete investigation into the wells and springs of Connecticut.

An introduction to the former volume gives a brief *résumé* of the scope of investigations and the purposes of the work, with a description of the field methods employed for measuring stream flow, from which it appears that the system most generally in use is that of gauging by means of sectional areas and velocity readings. These last are taken by the Price current meter. Fig. 1 illustrates in a typical manner the plan of operations. At the selected station the river bed is divided transversely into any convenient number of points, at which records are taken both of the depth and the velocity. The latter is determined by two observations in each case, at one-fifth and four-fifths of the total depth respectively. The average of these two readings gives the mean velocity of the current very closely for open-water conditions. The discharge is obtained by a simple computation of the cross-sectional area of the strips multiplied by the average of the mean velocities at their ends.

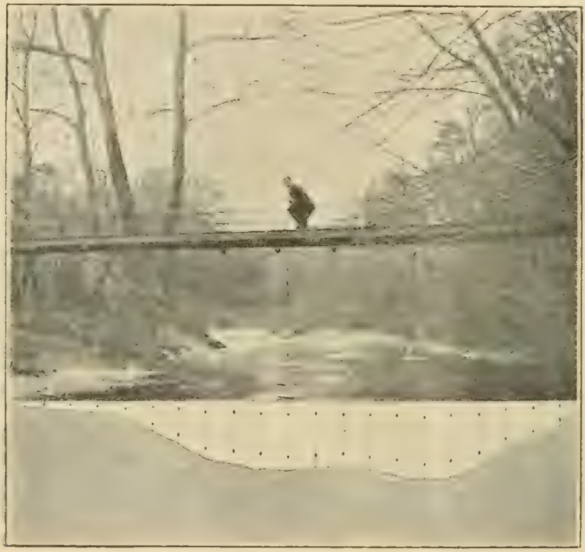

FIG. 1.—Bridge Station and Cross-section of Stream.

The second volume contains interesting chapters on the physiography, meteorology, and geology of the State of Connecticut, and not the least valuable feature is the study by Mr. Ellis of the conditions affecting the occurrence of water in crystalline rocks. The term crystalline is taken as covering both igneous (granite, diabase, gabbro, &c.) and metamorphic (schists and gneisses) varieties. More than two-thirds of the area of the State is underlain by rocks of this type, and a large number of wells have been driven into them. It is pointed out that the porosity of crystalline rock is very slight (averaging 0·5 per cent. or less), and that the only circulation of water which has sufficient rapidity of movement to be of value as a source of well supply must be through joints and fractures. A study of the occurrence of these joints, accordingly, is of great utility and value, and the data collected cannot fail to prove of more than local interest on account of the scarcity of information on the subject. B. C.

RECENT WORK OF GEOLOGICAL SURVEYS.

I.

GREAT BRITAIN AND INDIA.

THE wide range of work done by the Geological Survey of Great Britain is again seen in the "Summary of Progress for 1908" (1909, price 1*s*.). The numerous notes made on observations in England, Wales, and Scotland are, of course, only preliminary to their development in future memoirs; but we may here direct attention to the careful re-examination of two marine Devonian intercalations in the Upper Old Red Sandstone near Milford Haven (p. 35), and to the description of the Achanarras beds (Middle Old Red Sandstone) of Caithness, by Mr. R. G. Carruthers (p. 87). Caithness has also yielded a mass of sandstone with Lower Cretaceous fossils (p. 62). Even if this proves to be transported, like the blocks of chalk in Aberdeenshire, it will remain a remarkable addition to our knowledge of the extent of the early Cretaceous sea. The Petrographical Department has shown the presence of nepheline in several rocks of the Midland Valley of Scotland (p. 44).

The memoirs published recently include one of economic importance on the water-supply of Bedfordshire and Northamptonshire, with rainfall-maps supplied by Dr. H. R. Mill (1909, price 4*s*. 6*d*.). Dr. Strahan has written a second edition of the memoir on the country around Newport, in the South Wales coalfield (1909, price 1*s*. 6*d*.), which shows how knowledge advances, even during a decade. An interesting break near the top of the Carboniferous Limestone is pointed out, and the Old Red Sandstone is now divided into an upper and a lower series. It is probably not generally known that the characteristic Upper Old Red Sandstone mollusc, *Archanodon jukesii*, was found near Talgarth in 1895, the specimens being now in the British Museum. A terse and effective account is given on p. 89 of the passage from the continental beds of the Trias in this district through the Rhætic shales to the marine Jurassic system, and a comparison is made between this complete sequence and that observable where the Cretaceous sea spread across the Weald.

The description of the geology of the country around Basingstoke (1909, price 2*s*.), accompanying the colour-printed Sheet 284 (1*s*. 6*d*.), has been entrusted to Mr. H. J. Osborne White. The area is a familiar one, at the junction of the London Basin and the great swelling rolls of Salisbury Plain. The chalk district was formerly strewn with sarsens, which have been traced to a sandstone in the Reading beds. The Plateau Gravels raise interesting questions of former river-courses, and it appears that the Wey basin (p. 90) has now captured waters that once brought Lower Greensand débris westward into the valley of the Loddon. The soft Eocene strata are responsible for considerable "mutability of the lines of drainage."

The memoir on the country around Bodmin and St. Austell, by Messrs. Ussher, Barrow, and MacAlister (1909, price 4*s.*), accompanies the colour-printed map, Sheet 347 (price 1*s.* 6*d.*). The tin and copper mines are described, with sections. Considerable interest attaches to the origin of china-stone and china-clay (p. 105); the former is an altered granite, in which kaolinisation is not an essential feature. It must not contain tourmaline, or minerals liable to discolour it. China-clay, on the other hand, must be a kaolinised product, and tourmaline can be washed out of it during its preparation for commercial use. Mr. MacAlister (p. 115) attributes the main kaolinisation to "moisture with fluorides emanating from the granite," while Dr. Flett (p. 118) believes in the greater potency of carbonic acid. Hence we are by no means at the end of this much-discussed question. The metamorphism of the Devonian rocks by a granite associated with the Hercynian folding furnishes interesting material. We wish that Mr. Barrow could have been restrained from promulgating the Anglo-Swedish word "calc-flinta" (p. 99), which can hardly be taken as a serious term. It appears, however, on the index to the map, where it has become classed, with associated altered sediments, as of igneous origin.

The Scottish branch of the Survey recalls the ancient state of things, when romance and argument by flood and field were to be sought northward of the Tyne. The memoir on Sheet 45, including Oban and Dalmally (1908, price 2*s.* 6*d.*), has for its frontispiece the Pass of Brander, through which the Atlantic always seems to call, across the rain-swept moorland under Cruachan. Mr. H. Kynaston, before his departure for the Transvaal, surveyed this region with Mr. J. B. Hill, and several other authors have joined in the present memoir. Much of the interest of the area is petrographical, but nowhere is the petrographer more dependent on the relations of the rocks as determined in the field. Take, for instance, the marginal features of the Cruachan granite (p. 83), or the pitchstone with cordierite, augite, magnetite, and spinel (p. 129), which results from the fusion of a phyllite by a Cainozoic dyke. Bibliographers should be warned that one of the authors of this memoir, Mr. H. B. Muff, changes his name henceforward to the ancestral form of Maufe. Under this guise he appears as joint author with his colleagues, Messrs. Clough and Bailey, of a very striking paper on the Cruachan and Glen Coe cauldron-subsidence, in the Quarterly Journal of the Geological Society for November, 1909. It is not too much to say that the researches of the Geological Survey have added to our appreciation of one of the grandest regions of the Highlands.

The memoir on Sheet 36, covering the seaboard of Mid-Argyll, is mainly by Messrs. Peach, Kynaston, and Muff (1909, price 2*s.* 3*d.*). Effective illustrations are given of the remarkable boulder-beds traceable above the limestone-zone of the metamorphic series. The reality of the break marked by this conglomerate is shown by its frequent inclusion of local rocks, such as the limestone blocks in the Garvellachs. Rocks from unknown sources also occur. The chapter (p. 43) on the epidiorites of the area, and on their origin as "pillowy" basic lavas, will be of value to geologists in many countries who have to deal with this group of modified rocks, in which a similarity of character has been thrust on materials of very various modes of upbringing. The slate quarries of Easdale have been studied in their economic aspect, and Mr. Muff contributes (p. 16) a valuable exposition of the relations of the various parting-planes to the folding of the rocks, which is applicable to many other cases difficult of interpretation, even in the field.

The Records of the Geological Survey of India contain evidence of a great variety of observations, ranging from economic materials to fossil remains. In the mineral field Dr. Bleeck deals with jadeite, which is extensively worked in a dyke or in detrital boulders by Chinese enterprise in Upper Burma (vol. xxxvi., p. 254). He concludes that pure jadeite consists of the (metasilicate) $NaAlSi_2O_6$, and that the dyke in the Kachin Hills originally consisted of nepheline, $NaAlSiO_4$, and albite, $NaAlSi_3O_8$. One molecule of each of these would produce paragenetically two molecules of jadeite. Albite occurs in both margins of the dyke, as is shown in the interesting section on p. 276, and these marginal zones contain blocks picked off from an adjacent amphibolite. It is presumed that the original magma was unusually rich in soda. Mr. Fermor (vol. xxxvi., p. 295) verifies by new analyses the view of Laspeyres, that psilomelane is a definite manganate of manganese, barium, iron, potassium, and hydrogen, based on the acid H_4MnO_5. Hollandite is crystallised psilomelane, while coronadite of Arizona is held to be a form in which barium is replaced by lead. Mr. P. N. Bose's account of the mineral resources of Rájiplá (vol. xxxvii., p. 167) describes the carnelian mines of Ratanpur, which have been worked for 400 years. The stones are coloured by heating on the spot. The date of Mr. Copland's report is not given, but we judge it to be about 1830. At that time the miners walked seven miles to the mines and seven miles back every day, "on account of the tigers with which the country abounds." In the same volume (p. 199) Mr. Fermor describes three new manganese minerals from India, vredenburgite, probably $3Mn_3O_4.2Fe_2O_3$, and highly magnetic; sitapárite, $9Mn_2O_3.4Fe_2O_3.MnO_2.3CaO$, with a bronzy colour distinguishing it from braunite; and juddite, a manganese amphibole. Specimens of all these may now be seen in the British Museum collections.

In physical geology we note Mr. J. C. Brown's description of the mud-volcanoes of the Arakan coast, Burma (vol. xxxvii., 1909, p. 264), which are produced by the bursting up of petroleum vapours, and which occasionally build up temporary islands in the sea. Sir T. H. Holland and Mr. W. Christie furnish an important paper on the origin of the salt-deposits of Rajputana (vol. xxxviii., 1909, p. 154). They show, in the first place, that the rivers flowing into the basins in which the salt accumulates in dry seasons contain an unusual amount of sodium chloride; secondly, that this is not likely to be washed out of older salt-beds; and thirdly, by actual experiments at Pachbadra, that the amount of salt passing a front 300 km. broad and 100 m. high during the four hot-weather months is some 130,000 tons. Mr. T. D. La Touche suggested in 1902 that the salt in the great plains might be added to by wind-borne drift, but the present writers conclude that this is the essential method of supply. The Rann of Cutch becomes actually crusted over with salt in the dry season; magnesium and potassium salts, being more soluble, are left behind in the unevaporated water (p. 168), and the sodium chloride, probably with gypsum, is carried inland. Small Foraminifera have been blown inland from the Cutch coast for 500 miles. The rains follow on the hot months, and the salt is washed into temporary lakes before it can be blown back by the return monsoon. The application of this striking instance to the Triassic lake-basins, formed under desert conditions (p. 183), makes it of wide importance. Judging from the immense stretches of pebble-beds in the European Trias, and from the signs of extension and recession of the lakes, flood-waters arising under monsoon influences may have prevailed in a region that was dry during a large part of the year. Gypsum beds like those of our Trias are found deposited from the seasonal lakes of north-west India.

Stratigraphy is represented by Mr. G. E. Pilgrim's investigation of Tertiary fresh-water deposits in Baluchistan and Sind (vol. xxxvii., p. 139), in which he divides up beds previously grouped as Siwalik into an Oligocene series with Anthracotherium and the allied Brachyodus, an Upper Miocene series with Deinotherium and Tetrabelodon, and an unfossiliferous series, which is probably Upper Pliocene. Unconformities occur between these series. Mr. C. S. Middlemiss, writing on the Gondwanas of Kashmir (vol. xxxvii., p. 286), suggests a re-arrangement of beds previously studied. He has found a new Lower Carboniferous horizon in the Lidar valley (p. 319), lower than the Panjal volcanic series. Above the Panjal series on the Golabgarh Pass he traces a section where Lower Gondwana plants (Gangamopteris, Glossopteris, &c.) lie beneath marine beds with a Middle Carboniferous fauna. This establishes (p. 296) the position of the Lower Gondwana beds in peninsular India, including the Talchir glacial series. No signs of glacial conditions, however, were observed in their representatives in the north. Mr. E. W. Vredenburg, in a paper on a hippurite-limestone in Seistan (vol. xxxviii., p. 189), points out that Seistan occupies a tectonic depression, the floor of which has been covered by the lacustrine Pliocene Gobi formation, the equivalent of the Siwaliks of India. This has been covered by later alluvium, but appears, highly inclined, on the margin of the basin, and earth-movements have probably continued into Pleistocene times.

Following on Mr. Yabe's recent review of the genus Fusulina, particularly in its Asiatic bearings, which was noticed in a previous article in NATURE, Mr. H. H. Hayden adds a critical and microscopic investigation in a paper on Fusulinidæ from Afghanistan (vol. xxxviii., p. 230). He shows good reason for the view that Fusulina is perforate, but urges that the appearance of its shell, and its minutely granular character under the microscope, should place it among the porcellanea. It does not appear, however, that the fossil porcellanea selected for comparison are in their original condition, seeing how quickly a granular calcitic structure arises in shells that were once composed of aragonite. Mr. Hayden regards the shell of a modern Biloculina as also similar, and as composed of calcite (p. 233). In the face of other determinations it will be well to suspend judgment before Fusulina becomes placed in a unique position.

In Palæontologia Indica, also published by the Indian Geological Survey, Dr. A. S. Woodward (vol. iii., Memoir 3) has described fish-remains from the Lameta beds of the Central Provinces, which fix the age of these beds between Danian times and the close of the Eocene period.

The Mysore Geological Department (Bulletin No. 4) has assisted the gravity observations of the Survey of India by the determination of the densities of a large number of specimens of hornblende schists obtained from mine-shafts nearly 3000 feet in depth. The unaltered rock, where it is below the zone of saturation by water, has a density of 3·00. The effect on the superficial zone of alternate wetting and drying in a tropical atmosphere is shown by its being regarded as "weathered" down to 100 feet, the density in the first 10 feet being 1·65, inclusive of air-spaces, and rising to 2·66 at 30 feet and 2·90 at 100 feet. The determinations give what are styled "apparent specific gravities" in soil-analysis, and the method of collection of the loose material in its field-condition in a measured box might have proved simpler than that actually adopted (p. 9). In vol. viii. of the Department's Records (for July, 1906, to June, 1907, received in November, 1909), Mr. B. Jayaram makes the now customary complaint (p. 84) that his oldest rocks in Mysore are hornblende-schists, into which gneiss, and subsequently pegmatite, have intruded. He presumes below this "an hypothetical archæan basement rock, say gneiss," but this is probably suggested out of deference to the text-books. His notes on rocks and minerals express a large amount of original observation, and he claims a secondary origin for his pyroxene-hornblende granulites (p. 99), without realising that he is thereby bringing them into line with those of Saxony, the nature of which was so long misunderstood. According to Dr. Smeeth, the State geologist (p. 15), there is a good deal to be yet learned about the origin of the Mysore laterites; but Mr. H. K. Slater's report on the Sorab Taluk (p. 31) has suggestive remarks on the relation of laterite to lithomarge, and of lithomarge to an original highly felspathic granulite, elsewhere referred to as a banded felsite or rhyolite. He believes that the same granulite (p. 49) passes, by impregnation with silica and iron oxide, into a brecciated chalcedony-hæmatite rock, which has been described, somewhat misleadingly, as a quartzite. This paper needs some press-correction.

The Reports of the Mineral Survey of Ceylon for 1907 and 1908 include the last work of Mr. James Parsons, whose tragic loss is recorded in that for 1908. Considerable attention is given to thorianite, and the monazite of Ceylon has yielded 10 per cent. of thoria. "Reconstructed" rubies, as well as beautifully cut gems of a glass rich in lead and thallium, are now being sold in Ceylon markets. Western science has much to answer for in the east. The useful relations between the Survey and the Imperial Institute in London are clearly seen in these reports, and the same feature is apparent in the Geologists' Annual Report of the Federated Malay States for 1908, in which tin-deposits are naturally of foremost interest.

G. A. J. C.

EDUCATION ABROAD AND IN ENGLAND.[1]

IN education, as in other matters, each nation must solve its own problems for itself. Every system of education should be the expression of national characteristics and adapted to national idiosyncrasies. Still, lessons which we can ill afford to neglect may be learnt from the study of developments in other countries, and in some respects it is much easier to ascertain what is being done abroad than at home. Thanks to the admirable series of special reports inaugurated by Prof. Sadler, we can make ourselves more or less familiar with the details of foreign education. With regard to England, we are not so fortunately situated; the Board of Education gives little or no information as to new and successful experiments, and its reports have mainly a statistical value. This lack of information as to the progress within recent years renders a comparison between English and foreign systems difficult and misleading.

Attention is commonly concentrated upon Germany and the United States. This is natural, having regard to their extraordinary industrial development during the past generation and the extent to which it may be attributable to their systems of education. With regard to Germany, it would be remarkable if a nation forced to repair the ravages of war by intellectual effort—you remember Humboldt's famous expression in 1807, "Der Staat mus durch geistige kräfte ersetzen was er an physischen verloren hat"—had not in the course of a century become pre-eminent in one or more departments; but when you test the value of the system you will find, I think, that the general balance is in our favour. The facilities for technical and scientific instruction are as great here as there, but where the German has the advantage is in the better quality of the pupils who attend those colleges and schools. This is entirely due to the excellence of their secondary education, and until we can make the Board of Education and the public realise that prolonged and sound general education is the essential antecedent to successful technical and scientific training, the quality of the material supplied to our technical and scientific institutions will remain inferior. By their regulations, the Board of Education seem hardly to appreciate the supreme importance of this. A course of four years compares most unfavourably with the courses at the Gymnasia and Realschulen, and it is a fatal mistake to allow that course to be shortened in any circumstances, or to permit individual pupils or special classes to follow a curriculum varying from the curriculum approved for the rest of the school. To remedy the glaring defects in our system of secondary education, and to place our pupils upon terms of equality with those in Germany, it is imperative to fix a higher standard and strictly to adhere to it.

Of the United States as a whole it is difficult to speak. Each State has its own system, and the only common characteristic is the lavish expenditure upon buildings and equipment. No one is more conscious than the American himself that the results are far from satisfactory.

In spite of this, however, valuable lessons may be learnt from America. We are indebted to them for the promotion of international congresses, which will be of universal benefit if they only succeed in the standardising of university education, which at present leads to endless misapprehension and confusion. We might, too, with advantage imitate their custom of holding frequent local inquiries with a view to the re-adjustment of existing methods so as to satisfy modern requirements. At the same time, they have done much to solve the problem of the connection between instruction and apprenticeship, the workshop and the school. The fundamental principle there is based upon the rational assumption that the proper and only way for a young man to learn the practical side of his profession, together with business details, is by working as a regular employee, and that the only place where he can learn properly the scientific and the cultural subjects is at a school under trained teachers. We need also a bureau of education as well organised and endowed as that at Washington to act as an imperial centre for information and advice.

---

[1] From a paper read at the North of England Education Conference, Leeds, on January 8, by John C. Medd.

For purposes of effective comparison, it may be well briefly to indicate the acknowledged gaps and apparent defects in our system, and the possibility of remedying them by the adoption of particular types of school and methods of instruction from other countries. It is by such an eclectic process that the Japanese are transforming themselves, and have gradually built up a system of education which, upon paper at least, leaves little to be desired. Notwithstanding the constant criticism levelled against the ancient universities and great public schools, I do not consider that they fail to realise their respective functions.

It is with reference to the ordinary secondary schools that the position is so unsatisfactory, and for their improvement we must, as I have already intimated, learn from Germany, or Holland, the burgher schools of which furnished the Germans with their models. Simultaneously, the facilities for promoting the easy passage of suitable pupils of all ranks from one type of school to another ought to be increased.

In elementary education as a whole we stand unrivalled, with the possible exception of Holland, where the methods of instruction are still as Cuvier described them, "au-dessus de tout éloge." It would be folly to expect the same standard of excellence in all schools, having regard to the infinite variety of conditions under which each school is conducted. The great need, commonly, is for more practical instruction, some relaxation of the regulations as to building and equipment for manual instruction and domestic science, and the introduction of a system of supplementary courses. We require, as Prof. Sadler has pointed out, a new type of school in which less attention is paid to purely literary subjects and more to the practical side.

The teacher is the most important factor. Upon his character, capacity, and sympathy the quality of each school depends far more than upon the public spirit of the local authorities and managers. His training is still too limited and hampered by the exigencies of the certificate examination. The normal schools of both France and Holland are conducted on far more enlightened principles. It is recognised that there are certain subjects, such as the theoretical and practical study of natural and physical science, which every teacher, whether destined for an urban or a rural district, ought to know. We do not want to create two distinct classes of teachers or to establish separate institutions for those who will have charge of country schools, but we do want the student during his period of training to become qualified to discharge all those duties which are involved in the modern conception of an elementary school. In Holland, for instance, every student has a systematic course of instruction in horticulture and the elementary principles of agriculture. In woodwork every student makes a complete set of the models of the Swedish Slöyd system and of objects required for other lessons, such as chisels, rulers, levers, and scales; models of tools or engines to assist in explaining different trades and industries; implements for the manufacture of linen and lace, &c. In addition, each student constructs an aquarium, terrarium, and a case for insects to be collected and attended to by himself. Beyond acquiring a mass of information invaluable to him in his profession, he learns how to make the apparatus necessary for object-lessons in the primary school.

The outstanding blot upon English education is the absence of any adequate provision for those who have completed the elementary-school course but do not proceed to a secondary school. To expend millions upon these children until the age of thirteen or fourteen, and then to turn them over to the education of the streets, is disastrous from every point of view. It is during the period of adolescence that the habits are formed which will determine the boy's or girl's whole future career. Cast adrift as they are in the vast majority of cases to rely upon their own resources, they constitute a grave social danger, swell the ranks of the unemployed, and gravitate to the workhouse or the gaol. It is computed that only one in six between the ages of fourteen and twenty-one are receiving any systematic instruction. Taking those between fourteen and eighteen, 2,000,000 out of 2,800,000 have done with education altogether. Minister after Minister of Education deplores this, but no practical steps have ever yet been taken by any Minister to remedy the evil.

Continuation schools, however, are not alone sufficient. A few trade schools have been established, but they should be the rule, and not the exception. The Ambachts or trade schools of Holland furnish a good example. Those admirable institutions owed their origin to private or local initiative, but are subsidised and inspected by the Government. The course usually lasts for three years, and the instruction is continuous throughout the year. The subjects naturally depend to some extent upon local circumstances, but generally include drawing, geometrical drawing, physics, mathematics, mechanics, wood and metal work, all taught technically and with the view of particular industries. In some cases instruction is also given in masonry, furniture and instrument making, painting and house decoration. The results are undoubtedly excellent. For some time artisans were a little jealous of this trade instruction, but now there is an increasing demand by them for lads who have completed the school course. It is intended that pupils should proceed direct from the primary school at the age of twelve or thirteen, and this is the usual custom. A few boys occasionally attend after leaving the intermediate schools or the gymnasia.

Now that the Board of Education has substantiated its claim to be the responsible authority for agricultural education, it would be wrong to ignore that question altogether. We are as far behind other nations in that respect as in the training and instruction of children when they leave the elementary school. In proportion to the agricultural population we have a greater number of advanced colleges than are to be found in any country, but for the rank and file of young farmers and smallholders facilities for acquiring that knowledge which today is essential to the successful cultivation of the soil can hardly be said to exist. We are constantly reminded of the agricultural prosperity of Denmark, but it is generally forgotten that that prosperity is due to the excellence of the people's high schools, which impart a sound secondary education, and which are free from any agricultural bias. The attempt to combine agricultural teaching with general education was quickly discarded by the Danes. What we require are winter schools and classes corresponding to those in Ireland and Holland, a few practical schools of agriculture of the type of those in France, and farm institutes of the character recommended by Lord Reay's Departmental Committee.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Dr. Robert Simon has been elected to the chair of therapeutics rendered vacant by the death of Prof. Foxwell.

Prof. J. W. Taylor has resigned the chair of gynæcology.

Mr. E. E. Fournier d'Albe has been appointed assistant lecturer and demonstrator in experimental physics to fill the vacancy caused by the resignation of Mr. F. W. Aston, who has accepted a post as assistant to Sir J. J. Thomson at the Cavendish Laboratory.

Mr. George Heaton has been appointed lecturer in operative surgery, and Dr. Edgar P. Hedley has been elected to a demonstratorship in chemistry.

Prof. Bostock Hill has been asked to act as a delegate to represent the University at the Congress of the Royal Sanitary Institute to be held in Brighton in September, and also at the International Congress on School Hygiene which meets in Paris in March next.

Prof. F. W. Gamble, F.R.S., has been appointed to represent the University at the eighth International Zoological Congress at Graz (Austria) in August.

CAMBRIDGE.—The Public Orator, Dr. Sandys, spoke as follows in presenting Dr. Mark Aurel Stein for the degree of Doctor of Science *honoris causa* on January 20:—

Adest vir scientiarum non minus quam litterarum de finibus proferendis bene meritus, qui Hungariae in urbe maxima natus, et inter Tubingenses Oxoniensesque linguis orientalibus eruditus, in imperio nostro inter Indos iam per annos plurimos scholis et collegiis nostris administrandis non sine laude praefuit. Ibi, tot laboribus occupatus, tempora tamen subsiciva (ut aiunt) fluminis Indi regionis montanae annalibus antiquis diligenter edendis et luculenter illustrandis non sine fructu dedicavit. Ibi, tot laborum per intervalla, itinera illa magna, Indiae proconsulis magni auspicio, est aggressus, unde gloriam maximam merito est adeptus. Olim, ultra Indiae terminos in regiones propiores prospere peregrinatus (ut alia praeteream), petram Aornon accuratius investigandam esse duxit, rupem illam praecipitem et abruptam "ab Hercule frustra obsessam," ab Alexandro post pericula plurima captam et Minervae Victoriae consecratam.[1] Idem viatoris antiquissimi vestigiis sacris ingressus,[2] Asiae in ipsa penetralia plus quam semel peregrinatus est. Illic, itinere longinquo in uno, regionis desertae ex arenis, quot "oppidum cadavera"[3] diu sepulta, quot tabellarum litteris priscis inscriptarum reliquias, per saecula longa quam tuto conservatas, eruit! In altero autem, regionem quam immensam minutissime permensus, quot tabulis pictis domi delineandam tradidit! Quot turres diu desolatas, quot imperii Sinensis olim latius porrecti propugnacula, dinumeravit! Quam ingentem librorum in quanta linguarum varietate scriptorum multitudinem, quam multa denique artium Graecarum, artium Asiaticarum monumenta, aut pictoris aut sculptoris manu antiquitus exornata, Britanniae in Museum maximum victor reportavit! Herculis praesertim et Minervae et Amoris imagines, olim gemmis insculptis in creta impressas, ab eodem inventas recordati, confitemur inventori tam strenuo, tam sagaci, tam amabili, neque Herculis fortitudinem virtutemque, neque Minervae prudentiam, neque Amorem ipsum, scientiarum et veritatis amorem incorruptum, defuisse.

Duco ad vos Asiae exploratorem impigrum, prudentem, perdoctum, virtutis antiquae exemplar bene nominatum, Marcum Aurelium Stein.

Mr. R. C. Punnett, superintendent of the Museum of Zoology, has been elected to the professorship of biology recently vacated by Prof. W. Bateson. Mr. Punnett took his degree in 1898, obtaining a first class in part ii. of the natural sciences tripos. He was awarded the Walsingham medal in 1900. He has also received the Thruston medal. For some time he held the Balfour studentship, to which he was elected in 1904. He succeeded Dr. Harmer as superintendent of the Museum of Zoology at the beginning of last year.

Prof. W. Bateson, who vacated an ordinary fellowship at St. John's College on resigning the professorship of biology, has been elected to an honorary fellowship.

The chairman of the special board for anthropology gives notice that Mr. Roscoe will give a course of lectures during the present term on the natives of Uganda. The lectures will be given on Fridays (commencing on Friday, January 28), at 5 p.m., in the lecture theatre of the Archæological Museum.

THERE is about to be introduced into Congress a Bill "to promote health and efficiency by the establishment in the United States Bureau of Education of a division for the collection of scientific data on physical education and for the dissemination thereof." The proposal originated at a recent convention of the National Education Association, which appointed a committee to direct the attention of Congress to the need of governmental action on the subject. The association emphasises especially the growing importance of physical culture in view of the increased tendency to the congestion of the population of America in cities.

THE first meeting of the newly formed London branch of the Mathematical Association will be held at the Polytechnic, Regent Street, on Saturday, January 29, at 2.45 p.m. Mr. A. W. Siddons (Harrow) will read a paper on the Board of Education circular on the teaching of geometry, and amongst those who will contribute to the discussion are Miss Home, Miss Gwatkin, Mr. G. St. L. Carson, Dr. T. P. Nunn, Mr. J. G. Hamilton, Mr. F. J. G. Whipple, and Mr. T. J. Garstang. There will be an exhibition of books and models. Those desiring to attend are requested to communicate with the honorary secretary, Mr. P. Abbott, 5 West View, Highgate Hill, N.

ACCORDING to the *Madras Educational Review*, Sir F. D. Lugard, the Governor of Hong Kong, has reported to the Government that Mr. H. N. Mody has offered to present the colony with the building necessary to start a university. A committee has been formed, with the Governor as chairman, to promote the undertaking. Mr. Mody's original offer was to give a sum of 30,000*l.* for this purpose, and a further 6000*l.* towards the endowment. Plans of the necessary buildings were prepared, and as the Director of Public Works estimated that the cost would not be less than 58,000*l.*, Mr. Mody undertook to provide them in accordance with the plans which he had approved, no matter what the cost might be, stipulating, however, that he should use on the buildings the 6000*l.* originally given for endowment if it should be required.

A COPY of the report of the principal of the Huddersfield Technical College for the session 1908–9 has reached us. The number of students in attendance during the session amounted to 1593, an increase of 106 over the previous year. The principal directs attention to the urgent national and civic importance of an early attempt to remedy by legislation the defects in our present system of public education. He points out that, after passing through the standards in the primary schools, most of the nation's children are cast adrift upon the world untouched by any educational influence, the great majority before they reach the age of fourteen, and many thousands before they are thirteen. There are in England and Wales more than 1,500,000 boys and girls below the age of seventeen who are not in attendance at any school, whether day or evening, primary, secondary, or technical. It is to be hoped that the need for the continued educational oversight and care of this army of adolescents will be recognised by our legislators speedily. Half-time labour below the age of fourteen, he insists, must be abolished, and the school-leaving age raised to fourteen at least, while some beginning should be made in the work of providing for the continued instruction of those children who at present escape from all educational supervision on leaving the day school.

THE *Builder* for January 15 has an illustrated article on the accepted design for the City of Leeds Training College. The portion of the estate of Kirkstall Grange, Far Headingley, near Leeds, which is to be utilised measures seventy acres in extent. The major portion has been purchased from Lord Grimthorpe, and about thirty acres have been leased for seven years. The existing house, a fine example of eighteenth-century work, is very wisely to be retained in the scheme. A finer site could hardly have been obtained. The scheme of buildings comprises educational block; five hostels for women and two for men, in addition to the existing mansion, which is to be utilised as a hostel for men; baths and laundry; sanatorium; principal's and vice-principal's houses; women's and men's games pavilions, together with the requisite lodges. Sir Aston Webb, as assessor appointed by the committee, placed the design of Mr. G. W. Atkinson first. The front elevation of the educational block in this design consists of a centre and two end pavilions connected by wings; crowning the centre, where a recessed portico of the Corinthian order standing on a basement is employed, is a low dome. The whole composition has an air of Georgian refinement which accords well with Kirkstall Grange, and the scheme, when translated from paper to reality, will make the educational apparatus of Leeds Education Committee as nearly perfect as is possible in the present state of our knowledge.

THE Maharaja of Durbhanga, presiding at the end of December last at the Lahore Industrial Conference, spoke of the industrial activities of India. The *Pioneer Mail* reports him to have said that the first and foremost of all Indian industries is agriculture. Agriculture is receiving the serious attention of the Government. Agricultural colleges and Government farms planted here and there have been doing fruitful work so far as they are able, but there are not enough of them yet to do more than touch the fringe of the subject. Scientific agriculture must begin to be taught and learned at all the primary schools in India, every pupil being practically instructed by means of gardens attached to each school. The agricultural education of the people must be put in the foreground of the endeavours of the Government and of all the educational authorities. Experiments at the Government farms have shown that with selected seed and proper treatment an acre can be made to yield, on an average, from 50 to 100 per cent. more than it does at present. To take an instance, the average output of wheat in India is only from nine to ten bushels per acre. In Great Britain it is more than thirty. To raise the average in India even to fifteen bushels is surely not beyond the reach of science. The same remarks might be made in regard to all the food crops. An attainable 50 per cent. more, when realised, would go far to banish scarcity and famine from the land.

[2] A reference to Hiuen-Tsiang, the great Chinese pilgrim of 649 A.D. whom Dr. Stein claimed as his "guide and patron-saint" ("Sand-buried Ruins of Khotan," ed. 1904, p. xxi., &c.).

[3] Ap. Cic. *ad Fam.*, iv. 5, 4.

Prof. Rudolf Tombo, jun., of Columbia University, contributed to *Science* of December 24 last an article dealing with university registration statistics in the United States. The returns are given for twenty-eight of the leading universities, three institutions having been added to the list this year, viz. Texas, Tulane, and Washington (St. Louis). In 1909 four universities—Iowa, Minnesota, New York, and Yale—showed a loss in enrolment compared with the previous year, as against two universities in 1908 and five in 1907. On the whole, there were considerable gains, the increase in several instances being quite marked. The greatest gains were made during the year by Columbia, Chicago, Wisconsin, California, Cornell, Ohio, and Pennsylvania, in the order named, each one of these having gained more than 300 students. Columbia was the only university to register an increase of above 400 students in 1909, whereas there were no fewer than eight in 1908. For the second time in the history of American universities the 6000 mark was exceeded, Columbia having a total enrolment in 1909 of 6132 students, Harvard having registered 6013 in 1903. Harvard continues to lead in the number of male academic students, being followed by Yale, Princeton, Michigan, Chicago, Wisconsin, Columbia, and Minnesota. A general depression occurred in the case of the engineering schools, Stanford being the only institution to exhibit a noteworthy gain. The important schools of agriculture showed an increase, the single exception being Minnesota. The article concludes with an individual examination of the statistics of the more important of the universities.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 20.—Sir Archibald Geikie, K.C.B., president, in the chair.—Dr. C. **Bolton**: Further observations on the pathology of gastric ulcer (progress report). In four previous papers the production and properties of gastro-toxic serum, obtained by immunising the rabbit with guinea-pig's gastric cells, were described, and it was demonstrated that the ulcers produced by the serum healed within three or four weeks if the animal were in its normal condition and fed on a normal diet. Since chronic gastric ulcer in the human subject is a common malady, and gastric ulceration is initially acute, it was considered that some unknown condition or conditions must be present which delay the healing of these ulcers. It was, however, found on experiment that so long as the stomach emptied itself in the normal time it was impossible to delay the healing of gastric ulcer by increased or diminished acidity of the gastric contents or by feeding on infected food; the position of the ulcer in the stomach did not materially affect the result. The present communication deals with the effects of interference with the motor function of the stomach upon the healing of ulcer, the food and acidity of the stomach contents being normal. The gastric ulcers were produced in the cat by the local injection of gastro-toxic serum into the stomach wall, the serum being prepared by immunising the goat with the gastric cells of the cat. Motor insufficiency of the stomach, leading to retention of its contents, which is one of the commonest forms of indigestion of food in man, was produced by constricting the pylorus of the cat by means of rubber tubing, the ulcer then being formed on the anterior wall of the stomach. It was found that in these circumstances the healing of the ulcers was delayed for at least twice the normal time. The ulcers, however, eventually healed up, but the regenerated mucous membrane was of a lower type than normal. Thus it may consist on the forty-first day of a single layer of cubical cells such as should be found on the tenth day of normal healing, or of glands formed entirely of duct epithelium. It was further found that the more sclerotic the base of the scar the more badly developed was the mucous membrane. In certain cases the *normal* healing of the ulcers was occasionally delayed by necrosis of the granulation tissue forming their bases, or by excessive formation of fibrous tissue, and in these cases the mucous membrane was of the lower type. It was therefore considered that the delay in healing in motor insufficiency was an exaggeration of the condition occasionally seen in the normal state. Both conditions are due to digestion or irritation of the base of the ulcer, leading to necrosis or increased formation of fibrous tissue, so that the regenerated mucous membrane is either unable to grow over it at all or only consists of a single layer of cells or of glands of a lower type than normal. When the base is excessively fibrous the glands have not a sufficiently vascular and cellular stroma in which to proliferate.—Dr. G. **Dreyer** and J. Sholto C. **Douglas**: The velocity of reaction in the "absorption" of specific agglutinins by bacteria, and in the "adsorption" of agglutinins, trypsin, and sulphuric acid by animal charcoal. Though a fair number of observations exist as to the influence of time on the so-called adsorption processes, *e.g.* the adsorption of a dye by a fibre (Bordet, Bayliss, &c.) proving that it takes a very considerable time before equilibrium is reached, the study of the time reaction in the taking up of agglutinins by bacteria has been confined to the observations of Eisenberg and Volk. These authors maintain that the velocity of reaction is extremely fast, and that equilibrium is reached in five minutes, even at a temperature of 0° C., and that no appreciable difference is to be found in the absorption velocity, whether the reaction takes place at 0° C. or 37° C. The present authors' results, which are contradictory to those of Eisenberg and Volk, may be summarised as follows:—(1) the establishment of equilibrium in the absorption of agglutinins by their specific bacteria is not attained, as stated by Eisenberg and Volk, in less than five minutes at 0° C., but takes a considerable time, since equilibrium is not reached at room temperature even in four hours; (2) the adsorption of agglutinin or trypsin by charcoal does not reach an equilibrium within four hours at room temperature, nor the adsorption of sulphuric acid by charcoal in twenty-four hours, or possibly even in forty-eight hours; (3) there is no justification for judging as to the nature of the interaction between an absorbing substance and a material absorbed from the rapidity or slowness with which equilibrium is attained, as has been done by Arrhenius.—Dr. G. **Dreyer** and J. Sholto C. **Douglas**: The absorption of agglutinin by bacteria, and the application of physico-chemical laws thereto. Eisenberg and Volk, in 1902, were the first to make more or less exact quantitative measurements of the absorption of agglutinins by bacteria. They showed that if agglutinating serum were treated in varying dilutions with a constant amount of homologous bacteria, the amount of agglutinin taken away was not constant, but that in a concentrated serum the absolute amount removed was greater than in a diluted serum, whilst, on the other hand, the relative amount taken away in a dilute serum was much the greater. By taking the experiments of Eisenberg and Volk, Arrhenius showed the existence of a relation between the quantity of absorbed agglutinin, C, and of the agglutinin left in the fluid, B, and expressed this relationship in the simple formula $C = kB^n$. The result of the present experiments may be summarised as follows:—(1) when an agglutinating serum in different concentrations is treated with constant amounts of bacteria, the quantity absorbed, C, may not only increase to a limit value, but may, when this point is passed, even decrease to zero when the concentration of the serum is further increased, which is quite different to the statement of Eisenberg and Volk; (2) it is impossible, from the greater or smaller size of the exponent "*n*" in the formula $C = kB^n$, to determine whether, in the case of agglutinin, we have to deal with an absorption or an adsorption process, as done by Arrhenius, as in both cases "*n*" may vary within nearly the same ranges; (3) the formula $C = kB^n$, proposed by Arrhenius to express the absorption of agglutinin by bacteria, as being a special example of the Guldberg and Waage law of chemical mass action, does not hold good either in the case of the absorption of agglutinin by bacteria or of the neutralisation of agglutinin by homologous bacterial filtrate; (4) the combination of agglutinin and bacteria is therefore not such a simple process as anticipated by Arrhenius, but is very possibly complex, and not improbably of the same nature as the interaction of bacterial toxins and anti-toxins.—V. H. **Veley** and A. D. **Waller**: Observations on the rate of action of drugs upon muscle as a function of temperature. The authors tested the problem by observations on the rate of action on muscle of alcohol, chloroform, quinine, and aconitine, at temperatures between 7° and 25°. They used Esson's formula, modified for their purpose, for the calculation of results,

$$\log L_0 - \log L_1 = m(\log T_1 - \log T_0)$$

(where L_0 and L_1 are the lengths of time between application of the drug and cessation of contraction, and T_0 and T_1 the absolute temperatures at which the action took place; m is the experimental constant). The values of m came out as follows:—alcohol = 20·5; chloroform = 14·3; quinine = 26·7. (The values of m in the case of hydrogen peroxide and hydrogen iodide = 20·38, and in that of chloric acid and ferrous sulphate = 26·5.) The corresponding temperature-coefficients per 10° are:—alcohol = 2·02; chloroform = 1·63; quinine = 2·52. (In a previous rough determination the authors found ether = 2.) The data from which the value of m was calculated in the case of chloroform are as follows:—

Temp.	Lengths of time.	$\log T_1/T_0$	$\log L_0/L_1$	m
7°	24·5′	0000	0000	
10°	21′	0017	0670	14·3
19°	13′	0182	2753	15·1
24°	10·5′	0257	3673	14·3
24°	11′	0257	3478	13·5

Mean = 14·3

The action of aconitine is completely arrested at 7°, and manifests itself as soon as the temperature is raised to 17°.—V. H. **Veley**: An examination of the physical and physiological properties of tetrachlorethane and trichlorethylene. Symmetrical tetrachlorethane, $CHCl_2CHCl_2$, was originally prepared about forty years ago from acetylene and chlorine gas in presence of antimony chloride. It is now prepared on a large scale by the same reaction, aluminium chloride being used instead of the antimony salt. Trichlorethylene, $CHClCCl_2$, is obtained from tetrachlorethane by heating with alkalies. Certain determinations of the densities and refractive index μ_a of tetrachlorethane have been published, but those of trichlorethylene have been curiously overlooked. Values are given of densities at certain temperatures and refractive index μ_D at 17° in the paper. The effects of both substances on isolated muscle are compared with that of chloroform. It is shown that toxicities of chloroform, trichlorethylene, and tetrachlorethane are in the ratio 1/1·5/4. It is further noted that the action of trichlorethylene is more regular than that of any other drug or anæsthetic examined by this method. Preliminary experiments with living animals have shown that anæsthesia produced by this compound is also of a very regular type.—J. D. **Thomson** and Prof. A. R. **Cushny**: The action of antimony compounds in trypanosomiasis in rats.—Sir David **Bruce**, Captains A. E. **Hamerton** and H. R. **Bateman**, and Captain F. P. **Mackie**: "Amakebe" (a disease of calves in Uganda).—Sir W. **Crookes**: Scandium. This is a continuation of the paper read in April, 1908 (Phil. Trans., A, vol. ccix., pp. 15–46), in which, after describing the mode of extracting scandia from the mineral wiikite, the principal salts, twenty-three in number, were described, their formulæ and analytical results being given in detail.

In the present paper the following salts are described, their preparation, analyses, and formulæ being given:—

Scandium Aurochloride, $3ScCl_3,2AuCl_3,21H_2O$.

Scandium aurochloride is prepared by mixing strong solutions of the component chlorides, and allowing the mixture to evaporate slowly over sulphuric acid in a vacuum desiccator. The double salts separate out in a felt-like mass of needle-shaped crystals of a yellow colour and very deliquescent. The water of crystallisation gradually goes off when the salt is kept in a desiccator over sulphuric acid, definite hydrates being formed. In this manner the following hydrates have been formed:—

8-Hydrate Scandium Aurochloride, $3ScCl_3,2AuCl_3,8H_2O$, and the

2-Hydrate Scandium Aurochloride, $3ScCl_3,2AuCl_3,2H_2O$.

By long-continued drying at 100° all the water is driven off, and the aurochloride melts to a clear orange-coloured liquid, solidifying to a crystalline mass on cooling. After keeping the salt for several days at 100° the liquid gradually becomes solid and crystalline, and in this state it is anhydrous, and has the composition $3ScCl_3,2AuCl_3$. Scandium platinocyanide, $Sc_2[Pt(CN)_4]_3 + 21H_2O$, is formed by the metathesis in the cold of scandium sulphate and barium platinocyanide. It crystallises out in large monoclinic prisms on a rhombic base, the angles of which are 81° 20′ and 98° 40′. They are very soluble in water, and are insoluble, or nearly so, in absolute alcohol, and frequently group themselves in rosettes. They are dichroic, crimson by transmitted light, and a rich metallic green by reflected light. The reflected and transmitted rays are oppositely polarised. Scandium iodate, $Sc(IO_3)_3 + 18H_2O$, is prepared by the metathesis of a soluble scandium salt with ammonium iodate. It forms a white crystalline powder almost insoluble in water. Scandium sulphite, Sc_23SO_3, is a white insoluble powder formed by mixing a soluble scandium salt with sodium sulphide. It is anhydrous, and gradually decomposes on exposure to dry air.

Scandium Malate,

$$\left.\begin{array}{l}CH(OH)COO\\ |\\ CH_2\text{——}COO\end{array}\right\rangle Sc(OH),H_2O.$$

Malic acid and scandium hydroxide react when rubbed together with a little water, and the liquid becomes clear on being heated. When gradually cooled a precipitate appears, and at the ordinary temperature of the laboratory the solution is opaque and almost solid. Scandium malate is a granular white powder, soluble in hot and difficultly soluble in cold water. It is easily soluble in ammonia, and is not precipitated from the ammoniacal solution by dilute acetic or malic acid.

Scandium Malonate,

$$CH_2\left\langle\begin{array}{l}COO\\ COO\end{array}\right\rangle Sc(OH)$$

Scandium hydroxide dissolves readily in a cold aqueous solution of malonic acid, and on being heated the solution deposits a semi-transparent granular precipitate, having no crystalline appearance under the microscope. This precipitate partially dissolves on cooling. If this solution is boiled for some time a dense precipitate is formed, which does not re-dissolve on cooling. According to the mode of preparation scandium malonate contains either one or two molecules of water:—

Mono-hydrated Scandium Malonate,

$$CH_2\left\langle\begin{array}{l}COO\\ COO\end{array}\right\rangle Sc(OH) + H_2O,$$

and

Di-hydrated Scandium Malonate,

$$CH_2\left\langle\begin{array}{l}COO\\ COO\end{array}\right\rangle Sc(OH) + 2H_2O.$$

Basic Scandium Malonate,

$$CH_2\left\langle\begin{array}{l}COOSc(OH)_2\\ COOSc(OH)_2\end{array}\right.$$

When a large excess of scandium hydroxide is gently warmed with an insufficient amount of malonic acid to dissolve it, and the filtered solution is well boiled, a basic salt is precipitated having the above composition.

Scandium Tartrate,

$$\left.\begin{array}{l}CH(OH)COO\\ |\\ CH(OH)COO\end{array}\right\rangle Sc(OH).$$

Scandium hydroxide is added to a strong solution of tartaric acid with slight warming until the greater part of the scandium hydroxide is dissolved, care being taken to keep the base in slight excess. The turbid solution is filtered and boiled. A granular precipitate comes down.

This is well washed with boiling water and dried in a desiccator over sulphuric acid. Formed in this way, scandium tartrate forms a white crystalline powder, insoluble in hot and slightly soluble in cold water, and insoluble in alcohol.

Scandium Racemate,

$$\begin{matrix}\mathrm{CH(OH)COO} \\ | \\ \mathrm{CH(OH)COO}\end{matrix}\!\!>\mathrm{Sc(OH)},4\mathrm{H_2O},$$

is prepared in a similar manner to the tartrate. The two salts are, however, not quite similar, as the racemate comes down less plentifully on boiling, and it is not anhydrous as is the tartrate, but contains four molecules of water, one of which is driven off at 115°.

Scandium Lævo-tartrate,

$$\begin{matrix}\mathrm{CH(OH)COO} \\ | \\ \mathrm{CH(OH)COO}\end{matrix}\!\!>\mathrm{Sc(OH)},2\mathrm{H_2O},$$

is prepared in a similar way to the tartrate. When dried in a desiccator over sulphuric acid it contains one molecule of water. Dried in the air it contains two molecules of water.

Scandium Meso-tartrate,

$$\begin{matrix}\mathrm{CH(OH)COO} \\ | \\ \mathrm{CH(OH)COO}\end{matrix}\!\!>\mathrm{Sc(OH)},\mathrm{H_2O},$$

is prepared by gently warming a slight excess of scandium hydroxide with aqueous meso-tartaric acid, and then boiling the filtered solution. The meso-tartrate comes down as a white granular precipitate. The analysis of the compounds of scandium with tartaric acid and its isomers has been complicated by the tendency to form basic salts admitting of no simple formulæ. Thus both the tartrate and lævo-tartrates occasionally form salts containing percentages of scandium ranging near to 23·5, with a deviation of two- or three-tenths of a unit one side or the other. The nearest basic salt which contains such an amount of scandium has the composition

$$5\left\{\begin{matrix}\mathrm{CH(OH)COO} \\ | \\ \mathrm{CH(OH)COO}\end{matrix}\right.\!\!>\mathrm{Sc\ OH} + \begin{matrix}\mathrm{CH(OH)COO{\cdot}Sc : O} \\ | \\ \mathrm{CH(OH)COO{\cdot}Sc : O}\end{matrix}$$

and contains 23·49 per cent. of scandium.

Linnean Society, December 16, 1909.—Prof. E. B. Poulton, F.R.S., vice-president, in the chair.—Rev. T. R. R. **Stebbing**: (1) Report on the Crustacea Isopoda and Tanaidacea collected by Mr. Crossland in the Sudanese Red Sea; (2) Isopoda from the Indian Ocean and British East Africa. Among the Red Sea species the most interesting novelty is one named *Lanocira latifrons*, in allusion to the peculiar widening of the frontal process. In British East Africa, Wasin has yielded a new genus and species meriting the significant appellation *Kalliapseudes makrothrix*, which may be rendered in the vulgar tongue as the "long-haired beauty of the Apseudidæ." The species is remarkable for the extensive fringes of feathered setæ on the mandibles, maxillipeds, and first gnathopods, as well as for the short round-ended finger of its second gnathopods. In the Stanley Gardiner collection the new species *Apanthura xenocheir* is unique within its own family in the structure of the hand and finger of the first gnathopods. The new genus and species *Pontógelos aselgókeros*, of the family Eurydicidæ, from Mauritius, displays a prolongation of the first antennæ hitherto unexampled in that family. Several new species and a new genus of Epicaridea, isopods parasitic on other crustaceans, are described from specimens transmitted by Miss M. J. Rathbun, who had extracted them with great care from the crabs of the Stanley Gardiner Expedition. In one instance it proved that the maternal pouch of the parasite was occupied, not by the usual enormous mass of eggs, but by another parasite, probably itself an epicaridean, though strangely metamorphosed. The discussion of this difficult tribe was opportune for offering a tribute of respect to the memory of the late Prof. Alfred Giard, one of whose latest writings was a luminous essay on Lamarck and Darwin.—Prof. G. H. **Carpenter**: Pycnogonida from the Red Sea and Indian Ocean, collected by Mr. Cyril Crossland.—R. **Shelford**: A collection of Blattidæ preserved in amber, from Prussia.—A. W. **Waters**: The Bryozoa from collections made by Mr. C. Crossland, part ii., Cyclostomata, Ctenostomata, and Endoprocta. The collections dealt with only contain sixteen species, and these are nearly all known from the Mediterranean, while nine are British. In this and the previous paper ninety-nine Red Sea species and varieties are referred to; of these, 34 are known from the Atlantic, 26 from British seas, 39 from the Mediterranean, 34 from Indian and neighbouring seas, 17 from Crossland's Zanzibar collection, 8 from Japan, 35 from Australia. The classification of the Ctenostomata is examined, and it is considered that the group Stolonifera of Ehlers must be divided into Vesicularina and Stolonifera. In the first there is usually a moderately thick erect stem from which the zoœcia arise directly, and they all have gizzards, an organ not general in the Ctenostomata, and probably confined to this group. In the Stolonifera as now reduced there is a delicate creeping rhizome expanding at intervals, and from these places the zoœcia arise, usually in pairs. There is no gizzard. The gizzards of the Vesicularina usually have a large number of sharp and irregular teeth surrounded by a band of strong muscles, but in Cryptopolyzoon the gizzard has but two teeth with nearly flat edges.

Geological Society, January 12.—Prof. W. J. Sollas, F.R.S., president, in the chair.—C. I. **Gardiner** and Prof. S. H. **Reynolds**; with a palæontological appendix by F. R. C. **Reed**: The igneous and associated sedimentary rocks of the Glensaul district (County Galway). The general succession of the rocks of the Glensaul district is given, in descending order, in tabular form. The graptolitic beds occurring in the Mount Partry beds have yielded nineteen species, which indicate the upper part of the zone of *Didymograptus extensus*. The commonest species met with are *D. extensus*, Hall, and *D. bifidus*, Hall. In a previous description of the rocks of the Tourmakeady district, the term Shangort beds was applied to a series of grits and tuffs, and the term Tourmakeady beds to an associated series of calcareous strata which generally take the form of limestone-breccias. In the Glensaul district it is not possible to draw a sharp line of distinction between the two rock-types. The fossils from the Shangort and Tourmakeady beds show a close resemblance to those of the Tourmakeady district, but the finding of certain additional forms, especially *Nileus armadillo* and Niobe sp., has impressed the close connection between this fauna and that of the Orthoceras Limestone of Sweden, and it is rather of Arenig than of Llandeilo age. The conclusion is in conformity with the field evidence. The relegation of the Shangort and Tourmakeady beds of Glensaul to the Arenig would imply a similar age for those of the Tourmakeady district. The Glensaul district contrasts strongly with that of Tourmakeady as regards the character of the crystalline igneous rocks, which are all quartz-felsites. One species of Illænus, one of Niobe, one of Nileus, two of Bathyurus, three of Cheirurus, one of Pliomera, one of Encrinurus, one of Phacops, and a new species of Bathyurellus are described; also three species of Orthis, one of Hyolithes, one of Rafinesquina, one of Camerella, and one of Porambonites.—Prof. E. W. **Skeats**: The gneisses and altered dacites of the Dandenong district (Victoria), and their relations to the dacites and to the granodiorites of the area. The area described lies about twenty-five miles south-south-east of Melbourne. The early geological surveyors regarded the dacites as Palæozoic "traps" passing into the granodiorites. Prof. J. W. Gregory described the rocks as dacites, probably of Lower Tertiary age, resting upon the denuded surface of the granodiorites and of the adjoining Lower Palæozoic sediments. The field-relations of the rocks are described, and gneiss is shown to occur between the dacite and the granodiorite. The contact with the plutonic rock is abrupt. No foliation or banding occurs in the granodiorites, but acid veins pass from the junction into the altered dacite and also cut across the foliations of the gneiss. The field-evidence shows that the dacites are older than the granodiorites, and also that the gneiss was formed before the intrusion of the acid veins. The chemical evidence indicates that differentiation of a magma took place; the dacite was first erupted, and, following on that, the granodiorite (of more acid composition) was intruded into the dacite. In the altered dacites a schistosity occurs near the contact, ilmenite is changed to biotite by reaction with the felspar in the ground-mass, biotite is corroded by the ground-mass, and hypersthene is altered at its margin to biotite and quartz. Finally, granules of blue tourmaline occur in the contact-rocks. In the gneiss, hypersthene is not found, ilmenite is rare, and the rock is foliated. The gneiss is probably a modification of the dacite, but evidence as to its origin is incomplete. It may be the result of extreme contact-metamorphism of a dacite of peculiar character, such as a tuff. Possibly it was produced by differential movement in the dacite before complete consolidation, and certainly before the intrusion of the granodiorite.—H. J. **Grayson**: Recent improvements in rock-section cutting apparatus. The apparatus comprises a slitting disc of mild steel and two bronze grinding laps mounted on a substantial wooden table. The discs and laps are each 10 inches in diameter, and revolve at about 900 revolutions a minute. The discs and laps are connected with endless belts, which in turn are connected with wheels driven by a 1-horse-power electric motor. Special clamps are used to attach the rock-specimen and to cut the slice. A goniometric crystal-holder, permitting of slicing in any desired direction, is described, and can be fitted to one of the clamps. Clamps swinging radially across the grinding laps permit the parallel grinding of the slice to any thinness. A polishing lap can be placed in the position of one of the grinding laps. The finishing of the slice is done by hand on a slate disc.

Zoological Society, January 18.—Prof. J. Rose Bradford, F.R.S., vice-president, in the chair.—S. A. **Neave**: Collections of butterflies made during four years spent in northern Rhodesia and adjacent territories. The collection comprised 450 species, of which thirty were new to science, besides several rare and little-known species, including the rare *Acraea mirifica*, Lathy, and the hitherto unknown female.—J. T. **Cunningham**: Marine fishes and invertebrates of St. Helena. The scientific results of a visit to the island in February and March, 1909, for the purpose of investigating the condition and prospects of the fisheries of the island. The author's report on the results of the investigation from the economic point of view has been presented to the Colonial Office. The invertebrates collected have been examined and identified by specialists of the Natural History Museum, namely, Dr. Calman, Mr. Edgar Smith, Prof. Jeffrey Bell, and Mr. Kirkpatrick, the last-named having described a new species of sponge and a new hydroid. The fishes have been worked out by the author himself, and include two new species, one belonging to the Stromateidæ and one to the Cyphosidæ. The three kinds of Albacore occurring at St. Helena are shown to be identical with the three species diagnosed at Madeira by the Rev. R. T. Lowe in 1839, namely, *Thynnus alalonga*, *T. albacora*, and *T. obesus*, species which have been confused or rejected by recent ichthyologists; the synonymy and distribution of these are for the first time correctly elucidated.—Dr. W. T. **Calman**: Second and concluding part of a report on new or rare Crustacea of the order Cumacea, from the collection of the Copenhagen Museum. This portion of the report deals with the families Nannastacidæ and Diastylidæ, and twenty-seven species are described, all of which are regarded as new, and three new genera are established.—Prof. W. M. **Smallwood**: Hydroids and nudibranchs of Bermuda.

Institute of Metals, January 19.—Sir Gerard A. Muntz, Bart., president, in the chair.—O. F. **Hudson** and E. F. **Law**: A contribution to the study of phosphor-bronze. This paper was intended to amplify the conclusions arrived at by A. Philip, who presented a contribution on phosphor-bronze to the Institute of Metals at the Birmingham meeting of the institute in 1908. The authors endeavoured to indicate the relation between the mechanical and other properties of the copper-tin-phosphorus alloys and their constitution and structure. A useful diagram was included in the paper showing the constitution of all the alloys containing up to 25 per cent. of tin. The paper included notes on the examination and analysis of the phosphor-bronzes, and was illustrated by a remarkably clear and numerous collection of photomicrographs illustrating the structure of the alloys. Many of these photographs were originally of 1000 diameters, and these were further enlarged by being projected on a screen from lantern-slides made from autochrome plates, the marvellous blue-green and red colourings of the various constituents thereby being brought before the notice of the audience in a very novel and effective manner.—T. Vaughan **Hughes**: The failure in practice of non-ferrous metals and alloys, with particular reference to brass loco-tubes. This was essentially a practical, as distinct from an academic, paper, and dealt especially with an investigation into the cause of a breakdown of brass loco-tubes which had led to serious casualties and a Government inquiry. The failure was found to be due to the formation of a "scale," only 0·05 mm. thick, which offered a resistance of 20 megohms to an E.M.F. of 250 volts when dry and 150,000 ohms when wet. This electrical measurement showed the heat conductivity of the scale, and explained the over-heating of the tube at the point where the breakdown had occurred.—C. O. **Bannister**: The use of carbonaceous filters in the smelting of zinc. The paper was a corollary of that entitled "Notes on the Production of Pure Spelter," by J. S. G. Primrose, read at the Manchester meeting of the institute in October, 1909. Mr. Bannister described particularly the filters used in the Hopkins fumeless zinc process. The process was stated to have begun with the object of producing lead-free zinc only, but it now embraced three objects—the manufacture of pure spelter, the prevention or reduction of zinc fume, and the obtaining of higher yields.

Royal Meteorological Society, January 19.—H. **Mellish**: Presidential address, on some relations of meteorology with agriculture. The close dependence of agriculture upon climate and upon the periodical variations of the weather has been recognised from the earliest times, but the relations are of such a complicated character, and the difficulty of separating the effects of the different factors is so considerable, that as much progress as might have been expected has perhaps not been made in applying the data of meteorology to the purposes of agriculture. The president first referred to the writings of various authors on the subject of temperature and rainfall, as affecting the wheat and other crops, and then proceeded to deal with such questions as the liability of some crops, and especially of fruit, to injury from frosts; the influence exercised by forests upon climate, and especially upon rainfall; and the study of phenology. He next considered what steps meteorologists could take to further the application of the data of their science to the various problems of agriculture. It is doubtful whether farmers make as much use of the forecasts and weather reports as they might. Possibly this may arise because they are not familiar with the technical terms in which the reports are necessarily couched. This might be remedied in the course of time if instruction on the subject could be worked into the courses at the agricultural schools and colleges. The Royal Meteorological Society has lost no opportunity of urging the importance of the subject to farmers, and also the inclusion of meteorology under the head of nature-study in the schools, and there are reasons to think that this is having some effect.

MANCHESTER.

Literary and Philosophical Society, December 14, 1909.—Mr. Francis Jones, president, in the chair.—Dr. S. **Russ**: A note on radio-active recoil. When radium emanation is condensed at the bottom of a glass tube from which the air has been removed, active deposit particles are radiated up the tube. This phenomenon has been attributed to the recoil of the atom when an α particle is ejected from it. A disc suspended above the emanation may be the recipient of the active deposit particles. An analysis has been made of the decay curves exhibited by such a disc when exposed for different times. The conclusions arrived at are that the numbers of Radium A and radium B particles projected from the emanation are about equal, and that in comparison with them the quantity of radium C projected is insignificant. This latter result has recently been shown experimentally by Dr. Makower and the author.—D. M. S. **Watson**: A preliminary account of the bibliography of the post-Triassic Sauropterygia.

January 11.—Mr. Francis Jones, president, in the chair.—Prof. F. E. **Weiss**: Variability in the flowers of Tropæolum hybrids. A year ago a Tropæolum was observed by Prof. Weiss which showed at the same period three types of flowers, some yellow, some yellow with red markings, and some completely claret coloured. There seemed no marked periodicity in the occurrence of these flowers in 1908, though sometimes the yellow and sometimes the parti-coloured flowers predominated; but in an offspring of this plant it was noticeable that the parti-coloured and red flowers occurred only during the fine, hot weather in the second week in August, while during the cold and wet periods of July, September, and October all the flowers were yellow. This indicated a determining influence of temperature and light, and it is borne out by experiments in self-fertilising the variously coloured flowers. In the second (*f2*) generation a variety of different plants arose by segregation, and the colour of the parental flower had no determining effect, yellow flowers yielding red offspring and *vice versa*. Incidentally, the segregation of characters in the second (*f2*) generation showed that in Tropæola, dwarfness is recessive to tallness, as is the case in sweet-peas, and that red sap is a dominant character, though sometimes not apparent owing to unpropitious external conditions. This potential redness is, of course, different from the latent condition of a recessive character, which cannot be called into evidence by external conditions.

DUBLIN.

Royal Irish Academy, January 10.—Dr. F. A. Tarleton, president, in the chair.—Sir Robert S. **Ball**: Contributions to the theory of screws, viz.:—(1) on the expression for the virtual coefficient of two vector-screws; (2) on the composition of twists or wrenches on vector-screws; (3) on the pitch operator,

$$\Delta = \frac{d}{dp_1} + \frac{d}{dp_2} + \ . \ . \ . \ + \frac{d}{dp_n}.$$

(4) applications of quaternions to the theory of screws; (5) use of quaternions in the theory of reflected screws; (6) quaternion investigation of the screw reciprocal to five given screws; (7) representation of screw systems of the third order by linear vector functions. The virtual coefficient of two screws α and β is

$$\tfrac{1}{2}\{(p_\alpha + p_\beta)\cos\theta - d\sin\theta\},$$

where p_α p_β are the pitches of the two screws, and d is the length of their common perpendicular. It is here explained how θ can be measured without any ambiguity when α and β are regarded as *vector-screws*. The pitch operator Δ can be applied to any general formula connecting n screws belonging to an $(n-1)$ system, and by successive application a group of new formulæ can sometimes be derived. The application of quaternions to the theory of screws is founded on Hamilton's theorem as developed by Joly, that if μ be a vector moment and λ a vector force, then $S\mu/\lambda$ is the pitch of the screw on which the wrench lies, and $V\mu/\lambda$ is the vector perpendicular from the origin on the screw. One of the most fundamental theorems in the theory of screws asserts the existence of one screw and, in general, only one screw reciprocal to five given screws. The expression is here given of the vector coordinates of the screw reciprocal to the five screws

$$(\mu_1, \lambda_1);\ (\mu_2, \lambda_2);\ (\mu_3, \lambda_3);\ (\mu_4, \lambda_4);\ (\mu_5, \lambda_5).$$

This is, as might be expected, a symmetrical form with regard to the five screws, and leads, among many other results, to a concise expression for the sexiant which when equated to zero gives the condition that six screws shall belong to a five-system. Joly showed that Hamilton's beautiful theory of linear vector functions receives its geometrical representation by the system of screws of the third order. The fundamental properties of linear vector functions can be explained as immediate consequences of the theory of screws.

PARIS.

Academy of Sciences, January 17.—M. Emile Picard in the chair.—E. **Bouty**: The electric cohesion of neon. Although the molecular weight of neon is intermediate between argon, the molecular weights, and helium, its dielectric cohesion is much lower than that of the latter. The dielectric cohesion of neon is lower than that of any known gas; from the point of view of the obstacle opposed to the electric discharge, 57 cm. of neon are equivalent to a layer of 1 cm. of air.—W. **Kilian**: A new example of phenomena of convergence in ammonites: the origins of the group *Ammonites bicurvatus*.—A. **de Gramont**: The distribution of the ultimate lines in stellar spectra.—A. **Demoulin**: The K systems and congruences.—M. **Cisotti**: An application of the method of Jacobi.—Ludovic **Zoretti**: Ensembles of points.—L. **Décombe**: The elimination of directing electric couples, and effects due to asymmetry, to the absence of regulation and to contact electromotive forces in quadrant electrometers.—Edmond **Bauer** and Marcel **Moulin**: The constant in Stefan's law and the radiation of platinum. In a recent paper the authors described a method of determining the constant σ in Stefan's equation $E=\sigma T^4$ by the comparison of the radiation of a black body at 1064° C. with the radiation of a platinum sheet, known, in absolute measure, by experiments in a vacuum. It was assumed that the radiation of platinum followed Lambert's law up to large angles of emission; the latter assumption has now been proved by experiment to be inaccurate, and the introduction of the resulting correction reduces the original value of σ from $6{\cdot}0\times10^{-12}$ to $5{\cdot}3\times10^{-12}$, a figure in good agreement with the $5{\cdot}32\times10^{-12}$ of Kurlbaum.—A. **Colson**: The difficulties of chemical bibliography. A reply to some criticisms of M. Baubigny.—E. **Kohn-Abrest**: The action of heat upon aluminium in a vacuum. Aluminium is volatilised appreciably at 1100° C. in a vacuum, setting free silicon from the walls of the tube if the latter contains a silicate.—G. **Charpy** and S. **Bonnerot**: The cementation of iron by solid carbon. In these experiments both the iron and the carbon were submitted separately to a prolonged heating in a vacuum until no trace of gas was given off. The iron and carbon were then heated in contact at 1000° C., in a high vacuum, for several hours. No trace of carbon was absorbed by the metal under these conditions, although cementation was produced if traces of air were present.—Pierre **Camboulines**: The action of the vapours of carbon tetrachloride on anhydrides and oxides. The action of carbon tetrachloride vapour upon thirty-three oxides was studied. Silica and boric anhydride were not attacked; in the other cases a reaction took place at temperatures between 215° C. (niobic anhydride) and 580° C. (chromium oxide), the pure chloride of the metal being formed, excepting with niobic anhydride, thorium, and uranium oxides. With these a mixture of chloride and oxychloride was formed. This reaction furnishes a good general method for the preparation of anhydrous metallic chlorides.—R. **Fosse**: The transformation of some aromatic alcohols into phosphinic acids by hypophosphorous acid.—Gabriel **Bertrand** and G. **Weisweiller**: Vicianose, a new reducing C_{11} sugar. By the action of a diastatic preparation extracted from *Vicia angustifolia* upon the cyanhydric glucoside vicianine described in a previous paper, a new reducing sugar has been isolated. It has the composition $C_{11}H_{20}O_{10}$, and is the first definite biose prepared by the diastatic hydrolysis of a glucoside.—Marcel **Guerbet**: The condensation of secondary butyl alcohol with its sodium derivative; 3-methyl-5-heptanol and an alcohol, $C_{12}H_{26}O$, result from this condensation.—A. **Verneuil**: The synthetic reproduction of the sapphire by the method of fusion. Blue sapphires, possessing the colour and optical properties of the natural stone, have been prepared by heating alumina containing 1·5 per cent. of magnetic oxide of iron and 0·5 per cent. of titanic acid in the oxyhydrogen blowpipe.—A. **Conte**: Anomalies and spontaneous variations in the domestic birds.—Louis **Masson**: The tolerance of bacteria to antiseptics. Three species, *B. pyocyaneus*, *B. subtilis*, and *B. anthracis*, were grown in cultures containing small amounts of antiseptics (resorcinol, salicylic acid, copper sulphate, and mercuric chloride), and the proportion of the antiseptic was increased in successive cultures. The bacteria adapted themselves to increasing amounts of the poison, and attained a maximum resisting power, followed by a rapid fall, losing the whole of the acquired resistance. The tolerance was thus shown to be a temporary phenomenon, an example of the resistance of the species to variation.

CALCUTTA

Asiatic Society of Bengal, January 5.—Hem Chandra **Das-Gupta**: A probable identity between *Clypeaster complanatus*, Duncan and Sladen, and *C. duncanensis*, Noetling. The author gives reasons for thinking that *C. duncanensis*, Noetl., was founded on large specimens of *C. complanatus*, Duncan and Sladen.—I. H. **Burkill**: Fashion in iron styles. A paper to show that the iron styles used in India for writing on palm leaves are of different types in different parts of the country. The iron styles of the extreme south-west are heavy; those of the centre of the Coromandel coast are peculiarly long and generally light; those of Orissa are quite characteristic; the type which is like a clasp-knife is confined to the south. The paper is a supplement to the account of Indian pens published recently in the Agricultural Ledger, No. 6, of 1908–9.

DIARY OF SOCIETIES.

THE DEVELOPMENT OF GLASS-MAKING IN JENA.

Die Glasindustrie in Jena. Ein Werk von Schott und Abbe. Geschildert von Eberhard Zschimmer. Mit Zeichnungen von Erich Kuithan. Pp. 160. (Jena: Eugen Diederichs, 1909.)

THE history of the firm of "Otto Schott und Genossen" may be said to commence from the date of May 27, 1879, when Otto Schott first addressed from Witten, in Westphalia, to Ernst Abbe, professor and director of the observatory in Jena, a letter relating to some experiments he had recently been making in the production of lithium glass. He wrote:—

> "Recently I produced a glass into which was introduced a considerable amount of lithium, and of which the specific gravity was relatively low. I anticipate that this glass will show, in some direction or other, exceptional optical properties, and would ask you whether you are prepared to examine it as regards its refractive and dispersive qualities to determine whether my anticipation is correct."

The glass had been made in a small experimental furnace of Schott's design. The mixing was imperfect, and Abbe's report was to the effect that the glass contained too many striæ for optical determinations to be made. It was not long before this difficulty was surmounted, and with stirrers made from the stems of Dutch clay pipes, Schott succeeded in producing in small quantities in the laboratory experimental meltings homogeneous enough to allow of a complete determination of their optical properties. This determination, however, brought a new disappointment; for the secondary spectrum of an objective in which the crown glass of Fraunhofer was replaced by the new lithium-crown was more pronounced than before. The lithium glass, indeed, showed exceptional properties, but they were not in the direction desired.

The work was not immediately continued. A year elapsed before Abbe urged that it should be resumed. Schott thought of State aid, but Abbe, more experienced, represented the uselessness of applying for help from public funds until laboratory results of promise had been reached. In a letter of December, 1880, he suggested the main products to be desired from the point of view of technical optics.

(1) Crown glass of appreciably lower mean dispersion than that yet known, or of higher refractive index with the same dispersion.

(2) Flint glass the relative dispersion of which in passing from red to blue agrees more closely throughout the spectrum with that of crown (thus giving smaller secondary colour aberrations).

(3) Flint glass of very high dispersion, but of smaller mean refractive index.

The work was re-commenced on a more comprehensive scale. A systematic examination of glasses of varying composition was planned. To Schott, however, the procedure seemed to promise to be too protracted, and here his general chemical knowledge, and especially his acquaintance with mineralogy, served to shorten the path. Almost instinctively he fixed on the addition of phosphates and borates as the substances most likely to give glasses of novel character. As is well known, his intuition proved correct, and resulted in the foundation of a new industry. On October 7, 1881, Abbe, in sending greetings on the one-hundredth melting, writes:—"The problem of the complete achromatisation of the telescope objective I regard as solved by the two meltings 78 and 93"—two borate glasses.

The next step was the industrial realisation of the results proved possible in the laboratory. For this capital was needed, but in January, 1882, a "Glastechnisches Laboratorium" was founded in Jena by Abbe and Schott, in conjunction with Carl Zeiss and Dr. Roderich Zeiss. It was just at this time that Dr. Wilhelm Förster, director of the observatory and of the Normalaichungskommission in Berlin, was pressing that the Ministry of Finance should give State aid to an industrial research to determine satisfactory glass for the making of thermometers. In February, 1882, the Jena company became acquainted with Förster's aims. It was a matter of course that Schott should be asked to carry out the new investigation. Preceded by an examination of the varieties of thermometer glass then in use, Schott's new experimental meltings began in March, 1883, and by the end of the year promised so well that on this side also the question of the foundation of a new industrial undertaking merited serious consideration. In January, 1884, the promoters entered into new articles of association, with a capital of 60,000 marks, and, with the value of the work urged on them by various physicists of eminence, the Prussian authorities contributed, in the first two years, a further sum of 60,000 marks.

The present work was written to celebrate the twenty-fifth year of the life and development of the Jena glass works. Dr. Zschimmer's volume gives a popular account, not only of the circumstances which led to the foundation of the world-famous works, but of the technico-scientific problems which, in virtue of the researches there undertaken, have one after another been successfully solved. The relation of chemical composition to optical properties, the questions of homogeneity, durability, freedom from mechanical strain and from colour, these and all the main questions connected with the production of glass for scientific purposes are dealt with in a manner which renders them intelligible to the ordinary reader who is not specially interested in the scientific problems involved.

The processes of manufacture, the various types of furnace, the fabrication of the melting-pots, the methods of production of glass vessels of various forms, glass tubes, &c., the machinery for the production of glass bottles, the manufacture of gas-mantle cylinders, and other problems rather of a technical than a scientific character, are also dealt with. The special socialistic organisation of the undertaking—in common with that of the Zeiss firm—is shortly described.

The book is printed in a clear antique type and well illustrated with woodcuts of the style of the early days of printing, among which the excellent portrait of Schott himself calls for special mention.

THE MILLAIS GAME-BIRDS.

The Natural History of British Game Birds. By J. G. Millais. Pp. xi+142; illustrated. (London: Longmans, Green and Co., 1909.) Price 8*l.* 8*s.* net.

THE elaborate style in which Mr. Millais produces his more ambitious works renders it necessary that each should be restricted to a comparatively small group, as otherwise the price would be prohibitive to ordinary purses. In the present magnificent volume, which forms a companion to the "Natural History of the British Surface-feeding Ducks," the author has had a splendid opportunity for his artistic talents, as few birds offer finer subjects for illustration than do the members of the grouse and pheasant tribes. Not content with his own powers as an artist, Mr. Millais has secured the cooperation of Mr. Archibald Thorburn, and the combined efforts of these two great bird-painters have resulted in the production of a series of coloured and other pictures which it would be practically impossible to surpass, or even to equal, in effect, beauty of colouring, and general truthfulness to nature.

Too often artistic efforts of this kind are more or less completely marred in the process of reproduction, but in this instance Mr. Millais, as he tells us in his preface, has been fortunate enough to discover a method of reproduction which, in his opinion, far surpasses the best chromo-lithography or three-colour process. This opinion, so far as our experience permits, we are disposed to endorse; and we have certainly seen nothing to equal, let alone surpass, the frontispiece of black grouse, or the plate of red grouse in the red spring phase of plumage. In the coloured plates the birds are for the most part depicted in more or less quiescent poses; but in several of the monochrome plates we have in many instances abundance of action. Among these pictures of active bird-life, special attention may be directed to the two depicting, respectively, the courtship of the grouse and the playing-ground of the ptarmigan.

Possibly, nay probably, the expert would detect errors in some of the plates in regard to the number of primary quills in the wings; but such details would certainly not be noticed by the ordinary observer, and probably not by the majority of sportsmen; and if there be errors in this respect, as we believe there are, they in no wise detract from the general effect of the exquisite pictures. Although the price may appear high, it can scarcely be regarded as excessive for such a magnificent volume, especially when the cost of production and the fact that the issue is limited to 550 copies are borne in mind.

Probably it was the author's intention to convey to his readers all the available information in connection with his subject; but two or three points are noticeable where he has failed in this respect. We cannot, for instance, find any mention of the fact that grouse shed their claws during the main moult; neither does there appear to be any reference to the statements current in Scandinavia as to blackcock burrowing in the snow during winter. More serious is the absence of any mention of the various plumage-changes in the red-legged partridge; and in the case of nearly all the species, much more might have been written about the plumage of the chicks. In connection with partridges, the designations of "common partridge" for the grey species and "common red-legged partridge" for the French bird are by no means satisfactory; grey partridge and red-legged partridge would have been preferable and sufficient.

With the very natural tendency common to all writers of monographs to make the most of their subject, Mr. Millais uses the term British game-birds in a very wide sense, although it must be confessed that in this particular instance it is certainly a difficult matter to know where to draw the line. The red-legged partridge, for instance, is known to have been first introduced into our islands only in the second half of the eighteenth century, and yet it certainly cannot be omitted from any work on British birds. The typical pheasant likewise appears to be an introduced bird, although there is evidence that it had become completely naturalised by the time of the Norman conquest, and there can be no question as to its right to be now included in the British fauna. The introduction of the ring-necked pheasant in the early part of the nineteenth century likewise renders it difficult to exclude that species or race from the British list. When, however, we find such birds as Hagenbeck's pheasant, the Mongolian pheasant, the Prince of Wales's pheasant, the Japanese pheasant, and Reeves's pheasant figuring as British birds, we are on much more debatable ground; and if these are entitled to any mention they should not, in our opinion, have been accorded separate headings.

The author, it may be mentioned, is a strong advocate for regarding closely allied geographical forms in the light of local races rather than distinct species, and consequently classes all the birds mentioned above, with the exception of Reeves's pheasant, as local forms of *Phasianus colchicus*. No doubt there is very much to be urged in favour of this view, although when such a markedly distinct bird as the Japanese *P. versicolor* is classed as a phase of *colchicus* it seems a little difficult to know where to stop.

As we have had to mention on previous occasions, whenever Mr. Millais steps out of his proper province he invariably makes mistakes. Instances of this are afforded on p. 77 of the volume before us, where we find Pikerni for Pikermi and Œmingen for Œningen.

With the above exceptions, we have nothing but unstinted commendation to bestow on Mr. Millais's latest work.

R. L.

THE MANUFACTURE OF LEATHER.

The Manufacture of Leather. By H. Garner Bennett. Pp. xxi+420. (London: Constable and Co., Ltd., 1909.) Price 16*s*. net.

IN this work the author has attempted to produce a volume which shall be a text-book to meet the needs of candidates for the examination of the City and Guilds of London Institute, and for the degree and diploma examination of the leather students of the Leeds University. The book is also evidently written for the use of the practical tanner who possesses a limited knowledge of chemistry. We do not think that the author has been altogether successful. The proportion dealing with the scientific aspect of leather manufacture (specially noticeable in the chemistry of the tannins), and the chapter on tannage of chrome leathers, stand out in brilliant contrast with the other part of the book, particularly with the somewhat sketchy and superficial chapters dealing with the practical tanning of sole, belting and harness leathers.

The first five chapters deal with the nature of the skins, fermentation, hides and skins, and water; the author then passes to the first practical process of leather manufacture, viz. soaking, describing the various processes employed. He next deals with the various methods of removing hair and wool, together with a full description of the tools and machinery used for the purpose. Chapter viii. deals with the deliming of hides, a process which has now become universal, owing to the increased technical and scientific knowledge. In chapters ix., x., xi., the author brings together in handy form the chemistry of the tannins, the tanning materials and the methods of analysis. The next chapter deals with the preparation of the tanning liquors and the manufacture of extracts. In this, the author has gracefully glided over a very important subject, and has not dealt with many of the important changes which take place in the leaching nor dealt with some of the most recent plants devised for this purpose. The whole subject of extract manufacture is referred to in two printed pages, whereas on such an important subject as the manufacture of extract, which now forms almost 50 per cent. of the material for modern sole-leather tannage, it might have been expatiated upon at considerable length with advantage to the student.

The next chapters then deal with the tannage of sole, belting and harness leather previously referred to. In the chapters on the tannage of chrome leather but little detail has been given for the practical manufacturing process of this leather. The author then proceeds to the consideration of alum, fat, oil and aldehyde tannages, and to drying of leather, finishing of sole leather, currying and finishing of dressing leather, the dyeing and finishing of light leathers, and the finishing of chrome and other leathers. A special chapter deals with the enamelling and japanning processes and the dressing of wool rugs. This concludes the practical part of the book, at the end of which is a short chapter on the analysis of leather.

The scheme is comprehensive, but the author has failed to bring out any novel feature which has not been dealt with, at least equally satisfactorily, by other authors. The work cannot be looked upon as a standard text-book for the practical tanner, but may certainly appeal to those who, having a knowledge of practical leather manufacture, desire to study further the scientific principles.

The book is well illustrated by photographs of machinery taken from the well-known illustrated catalogues of leather trades' engineers. These do not show the essential features of the machines, but are simply photographic blocks; in no case are the essential principles of the machines described.

MEMOIRS ON MARINE ZOOLOGY.

Liverpool Marine Biological Committee's Memoirs. XVIII., Eledone. By Annie Isgrove. Pp. viii+105; 10 plates. Price 4*s*. 6*d*. net. XIX., Polychæt Larvæ. By F. H. Gravely. Pp. viii+79; 4 plates. Price 2*s*. 6*d*. net. (London: Williams and Norgate, 1909.)

THE editor—Prof. Herdman—is to be congratulated on adding these two useful memoirs to his well-known series. Miss Isgrove has given a clearly written account of a common cephalopod, for which she prefers to retain the well-known Lamarckian name rather than to adopt the name Moschites, which is its correct designation, according to the strict rules of nomenclature. In the first part of the volume interesting observations are recorded on the habits and food of this octopod, and on the conditions under which it has been found in the neighbourhood of Plymouth and Port Erin. Attention is directed to the great preponderance in number of the females, the relative proportion of the sexes of captured specimens being about fifty females to one male. In the following sections of the book the author gives an account of the external features and internal structure of the animal, considering each system of organs in turn. The morphology of the funnel, which is one of the most characteristic organs of the Cephalopoda, is worthy of more extended reference; the sections which deal with the foot and funnel contain no allusion to the homology of the latter with the epipodium of gastropods; this homology is merely parenthetically mentioned, fifty pages later, under the description of the pedal ganglia. The alimentary canal, the circulatory and excretory systems, the nervous and reproductive organs, and the spawning are carefully described, the account of the structure of the gills and the anatomy of the nervous system being worthy of special mention. In the section on the structure of the retina, the author speaks of a *nerve fibre* instead of a neurofibril, running along the axis of each retinal cell. The memoir is well illustrated by means of ten lithographic plates containing above eighty carefully drawn figures.

Mr. Gravely has essayed a difficult task, namely, to give an account of the polychæt larvæ which may be captured in the tow-net at Port Erin during the month of July. The complete identification of many of the larvæ so obtained is impossible, since their characters are totally different from those of adult worms. It is only exceptionally that such larvæ can be reared, in aquaria, to adults, and their identity definitely established. In many cases the larvæ do not present clear specific or even generic characters, and they can therefore be referred only to their respective families. The author has written a careful and detailed account, in most cases drawn from living specimens, of the principal larval forms captured, some of which have not been previously described. Measurements are given of the length and diameter of the larvæ, of some of the parapodia and setæ, and of the cilia; and the colour markings are recorded. The larvæ dealt with are as follows:—three Syllids, several Polynoids, three Phyllodocids (including Mystides and probably Eulalia), Nephthys, Spio, and four other Spionids, one of which is possibly the larva of the elusive Pœcilochætus, Polydora, and two other Polydorids, Magelona, Chætopterus, and Pectinaria, the metamorphosis, to the young adults, of the metatrochophoral larva of the last-named being described. The account of these larvæ, which is illustrated by means of forty-seven figures, will be welcome to many workers on plankton and on polychæts, and, although it is admittedly a preliminary account, it forms a good basis on which to found future observations. The reader is referred for a definition of the numerous technical terms employed in describing the different stages and larval organs to a recently published paper by the same author, but it would have been a considerable advantage and convenience to the reader if brief definitions of these terms had been given at the beginning of the present memoir.

We suggest to the editor of these memoirs that all the volumes published in the future be provided with a table of contents.

ENGINEERING SCIENCE.

(1) *Applied Mechanics, Embracing Strength and Elasticity of Materials, Theory and Design of Structures, Theory of Machines and Hydraulics. A Text-book for Engineering Students.* By Prof. David Allan Low. Pp. vii+551. (London: Longmans, Green and Co., 1909.) Price 7*s.* 6*d.* net.

(2) *Strength of Material: an Elementary Study prepared for the Use of Midshipmen at the U.S. Naval Academy.* By H. E. Smith. Second edition. Pp. ix+170. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 5*s.* 6*d.* net.

(3) *Stresses in Masonry.* By H. Chatley. Pp. viii+142. (London: C. Griffin and Co., Ltd., 1909.) Price 3*s.* 6*d.* net.

(1) THE subject covered by this book is a very extensive one, and the author is to be congratulated on the fact that by judicious compression, without sacrifice of clearness, he has in a volume of only 550 pages covered ground to which usually two or three bulky text-books are devoted. No student can expect, however, to make himself master of the contents of the book unless, as the author himself suggests in his preface, he works conscientiously through the sets of carefully thought-out problems which are given at the end of each chapter. At the end of the first, or introductory, chapter, Prof. Low has given a fairly complete bibliography for the subject, confining himself to works in the English language which have appeared during the last decade, or to those works which have been brought up to date by new and revised editions; this list will be found of considerable use by students who desire to extend their reading in any one branch of the subject.

The first five chapters are devoted to a series of introductory problems, work and energy, polygon of forces, moments and centroids, and for these latter both graphical and analytical methods are discussed; then follow six chapters on strength of materials. In the chapter dealing with compound strains and stresses, the opinion is expressed that in the case of ductile materials, such, for example, as mild steel, it is the resistance to shear which determines the strength, and reference is given to the experimental work of Guest, Hancock, Scoble, and others in investigating this problem. The whole of this chapter is well worth the careful study of the young engineer, who should not be content to leave it until he feels that he has made himself a thorough master of the principles laid down, and of the formulæ deduced for practical use in design work. Another chapter in this section which contains a well-arranged mass of information is that on the behaviour of materials in the testing machine; the latest memoirs have been summarised, and the conclusions to be drawn from these experimental investigations are clearly set forth.

In chapters xii. to xv. stress diagrams and the design of roofs and bridges are discussed, and, though of necessity there is much condensation, all the important points are clearly brought out. A student who has mastered this section will find that his work is much simplified when he comes to the study of one of the more advanced text-books specially devoted to this branch of engineering work.

The next eleven chapters are devoted to the subject of mechanism; such details as friction and lubrication, governors, toothed gearing, balancing of revolving and reciprocating masses, &c., are discussed in a satisfactory manner, and velocity and acceleration diagrams and crank effort diagrams receive due attention, though there is nothing novel in the method of treatment.

The last section of the book treats of hydraulics; the flow of water over weirs and through orifices and pipes, loss of head due to various causes, and the impact of jets on vanes are all in turn discussed, and the application of these principles to the design of such hydraulic machinery as water-wheels, turbines, pumps, and accumulators is then explained.

Prof. Low has succeeded in writing on a well-worn subject a text-book with many new features, and one which should find a place on the bookshelf of every young engineer.

(2) This small text-book was prepared for the use of the midshipmen at the U.S.A. Naval Academy in connection with one of the courses in the department of mathematics and mechanics. It deals, therefore,

only with the mathematical investigation of the subject; the experimental side is entirely omitted. The attempt to compress into one small table (p. 11) the average values of the tenacity, shearing strength, &c., of the chief materials of construction has led to the insertion of figures likely to mislead the unwary; for example, the tenacity of steel is given as 110,000 lb. per square inch; as a matter of fact, the tenacity of most of the mild steel used in constructional work lies between 60,000 and 70,000 lb. per square inch. Again, the shearing strength of wrought-iron is given as 20,160 lb. per square inch; this is much too low a figure; it is less than half the average value of the shearing strength of wrought-iron rivets and pins in double shear.

Each chapter has a series of examples to illustrate the formulæ which are deduced in that chapter, and the answers are in many cases appended; it is noticeable that these answers have a defect, by no means uncommon in text-books of this class, to which attention has often been directed, and which can best be explained by quoting a specimen answer. The student has to determine from certain data the diameter of a wooden spar used as a beam; the answer appended to the question is 7·0025 inches; of what value are the figures to the right of the decimal point? In a subject like strength of materials, one of the first lessons which the student should learn is that the numerical data which he proposes to use in some mathematical formula may, for obvious reasons, vary by some quite perceptible percentage on either side of a mean value (the value he proposes to use), and that, therefore, he can expect to obtain a solution which is only approximately correct, hence to work out a solution to the degree of accuracy of that in the example quoted above is not only a waste of time, but is positively misleading. It is to be hoped that in any future edition these answers will be revised.

The effect of combination of stresses is dealt with in chapter v. in a clear and simple fashion, and it is refreshing to find this portion of the subject taken up at such an early stage of the work, and its importance impressed upon the student.

The book concludes with a number of miscellaneous problems, such as reinforced concrete beams, stresses in thick cylinders and guns, &c.

The book will probably prove an acceptable one to young engineers who are just beginning the study of this important subject, and want to get a general insight into it before they begin to work at one of the more advanced and complete text-books.

(3) As the author points out, there are numerous elementary text-books on steel structural design, but there has been a distinct want of an elementary work on the design of masonry structures. This book will supply this need, for it explains just those underlying principles which the beginner finds it troublesome to understand.

It is difficult to follow the author's reasoning in chapter i., when deducing the safe compressive load for masonry; surely if it took 900 tons per square foot to crush a specimen of granite, there must have been a shearing stress when rupture occurred (most probably by shearing) of something like 450 tons per square foot, and, therefore, the method of deducing a safe compressive working stress given on p. 10 is hardly logical.

The branches of masonry design dealt with include walls, piers, brackets, simple arches, vaults and skew arches, domes, and retaining walls and dams; the treatment of each branch is sufficiently complete for all the practical cases the young civil engineer or architect is likely to meet with, all the more complex theories being wisely omitted.

The last chapter deals in brief fashion with reinforced concrete, the essential principles of this system being fully explained.

POPULAR NATURAL HISTORY.

(5) *Nests and Eggs shown to the Children.* By A. H. Blaikie, described by J. A. Henderson. Pp. xvi+78. (London and Edinburgh: T. C. and E. C. Jack, 1909.) Price 2*s.* 6*d.* net.

(6) *The Backwoodsmen.* By Charles G. D. Roberts. Pp. 317. (London: Ward, Lock and Co., 1909.) Price 6*s.*

(1) ALTHOUGH the title of this review of the above series of books might lead one to suppose that this book would be a popular account of the lives and habits of animals, it is unfortunately necessary to point out that such an idea would be fallacious. It is a matter of regret that the author should have chosen a title which, to our minds, does not convey a correct idea of the contents. The reason may be that we have been spoilt by the previous publication of one or two excellent little works on animal life, and that our criterion has been raised. Be this as it may, the author has not succeeded in doing justice to his theme, and we cannot imagine any young student being filled with enthusiasm for zoological science, still less agricultural science, after having had this introduction. That the author must be a botanist is evinced by such a word as "Crustaceæ" (p. 170). The illustrations are poor, Fig. 3 being especially crude; and an acknowledgment of the source of such figures as are taken from the publications of the U.S. Department of Agriculture, which are good, should surely be given under the figures, as is customary.

(2 and 3). These small books of the same series are marvellous examples of cheap printing, and are unaccompanied by the usual inferior illustrations; they are well illustrated, and, on the whole, are written in simple language. It probably would have been pre-

ferable to have substituted the description of a stickleback for that of a pike in the fauna of the pond as being more characteristic. We should think it rather doubtful whether most children (or grown-ups) would identify the frontispiece of the first of these two books as a hedge, nor should we wish the statement on p. 32 of the same book, that the "sap escapes and takes the form of curiously moss-like growths," to be taken as scientifically accurate by the student of natural history.

(4) Who could describe the butterflies to our children better than the Rev. Theodore Wood, who has done so much to popularise natural history among the young? We should expect that he would do it excellently, and are not disappointed in this little book, which is one of the best of the series. With the exception of one or two of the caterpillars, the illustrations are excellent, as is essential in a book of this nature, where a good coloured figure is so important; for no child could identify a butterfly correctly and with ease from the best of written descriptions.

(5) In describing the eggs of birds to the children it is an excellent idea to associate the nests with the eggs. Children do not dissociate the two to the extent that many older persons in the past have been accustomed to do. To a child as yet unspoilt by the collecting fever characteristic of youth, the nest is as important as the eggs it contains, and this small book will serve as an excellent guide to those budding observers to whom the finding of a nest is an object of interest and pleasure.

(6) Strictly speaking, this book, which is a collection of tales of the backwoods of Canada, does not come within our province; nevertheless, the author is so keen an observer of nature, and so well known as an ardent follower of the "call of the wild," that some of his tales are full of life and interest, and form excellent "light reading."

C. GORDON HEWITT.

OUR BOOK SHELF.

Recent Advances in Physical and Inorganic Chemistry. By Dr. A. W. Stewart. With an Introduction by Sir Wm. Ramsay, K.C.B., F.R.S. Pp. xiv+267. (London: Longmans, Green and Co., 1909.) Price 7s. 6d. net.

THE present volume is a companion to the author's book entitled "Recent Advances in Physical Chemistry." The issue of two such books by the same author affords a fair gauge alike of their merits and of their demerits. At the present time, no one writer can possibly be a master of organic, of inorganic, and of physical chemistry, and the criticisms that are offered by the author cannot, therefore, be regarded as having more than a superficial value. On the other hand, the production of a second volume so soon after the publication of the first may be taken as evidence of a considerable popular demand, and shows at least that a book of this type was called for by a wide circle of readers. In the circumstances, it is to be regretted that the publishers did not follow out the plan they have adopted in their excellent "Text-books of Physical Chemistry" and in their "Monographs on Biochemistry" of securing a series of articles by authors who have themselves worked on the subjects which they discuss. A volume compiled on these lines would have been of real value and undoubted usefulness.

In the present instance the author has rendered a service to the student who is working for an honours degree by presenting in a compact form the main results of certain lines of research which have been carried on in recent years, and may from time to time form the subject of examination questions. These investigations can only be mastered by a toilsome perusal of the original literature, and every attempt to reduce the labour involved in this task is sure of a welcome alike from the student and from the teacher. The danger of all such attempts is that the reader may acquire the indolent habit of obtaining his information in this easy way from second-hand sources, and so lose the stimulus and the opportunity of independent judgment which come from a perusal of the original text. On the whole, however, if the work is adequately carried out, the balance of advantage is in favour of the method of summarised presentation, and as the bulk of chemical literature becomes more and more unwieldy, the production of these summaries will become increasingly important. On these lines, Dr. Stewart's volume may be sure of a welcome and a considerable circulation.

(1) *The Elements of Mechanics of Materials. A Text-book for Students in Engineering Courses.* By C. E. Houghton. Pp. viii+186. (London: Constable and Co., Ltd., 1909.) Price 7s. 6d. net.

(2) *Experimental Mechanics for Schools.* By F. Charles and W. H. Hewitt. Pp. vii+288. (London: G. Bell and Sons, 1909.) Price 3s. 6d.

(1) IN this elementary text-book the engineering student is provided with a clear and concise account of the practical applications of mechanical principles to the design of simple machine parts and common structures. The first two chapters deal with the properties of materials as disclosed in the experimental laboratory, and with the strengths of tie-rods, cylinders, and riveted joints. Succeeding chapters relate to the strength and stiffness of beams, shafts, struts, and composite structures, including reinforced beams and columns; there is also an investigation of the effect of combined stresses. The most valuable parts of the book are the excellent collections of review questions and illustrative problems with which each chapter closes. These are very suggestive, well graduated, and eminently practical, and will be greatly appreciated by students and teachers alike. The author writes for those students who have only time for a very cursory study of the theory of elasticity, so that the limitations of the various formulæ are scarcely considered. The book will serve a very useful purpose, and will afford great assistance in some parts of practical design.

(2) Messrs. Charles and Hewitt describe or suggest a large number of simple experiments illustrating the principles of mechanics, and give extensive sets of examples in which these principles are enforced and applied. They constitute a mine from which teachers may select such details as are suitable for their own particular circumstances. The earlier experiments are statical, and deal with forces at a point, parallel forces, and friction, and illustrate the principle of the parallelogram and of the lever. A boy easily understands the action of a force because he employs his muscles every day to exert forces. The actions of couples remain more or less of an abstraction, for he seldom applies them. The authors have overlooked the need there is in the laboratory for the frequent muscular application of torques, measured by angular displacements in a simple torque meter placed between the hand and the apparatus.

Experiments in dynamics succeed those on statics, in which velocity, acceleration, inertia, work, kinetic energy, and centrifugal force are measured. The properties of vectors are here developed, though not so fully as might be desired, and occasionally there is a vagueness of language which must give trouble to a student who tries to think clearly.

Remaining chapters deal with the efficiencies of simple machines; the application of the link polygon; the drawing of reciprocal figures for jointed plane frames; and the determination of Young's modulus and of moments of inertia. In addition to the examples appended to each chapter, the authors give, at the end of the book, more than three hundred miscellaneous examples, and copies of recent examination papers, both theoretical and practical. A good index is provided, and teachers will find this book very helpful indeed.

Air and Health. By R. C. Macfie. Pp. vii+345. (London: Methuen and Co., 1909.) Price 7*s.* 6*d.* net.

THIS is a very readable work, containing much useful information. As the subject is dealt with in a manner which renders it interesting and easy of comprehension, even to people who may have no acquaintanceship with chemistry and physics, it should appeal to a wide range of readers; but it will prove of special service to the medical student of hygiene and preventive medicine, and the medical writer doubtless had this end mainly in view. The subject of the CO_2 respiratory impurity in the atmosphere is treated at some length. In this connection the author states (p. 133) that "Anyone who compares his power of mental work in a pure and in a CO_2 laden atmosphere, even if the latter be dry and cool, will find in the latter a considerable diminution, showing that at least nerve metabolism is affected." This statement implies that the CO_2 in a badly-ventilated room (as ordinarily understood) is capable, *per se*, of producing results which more recent experimental work demonstrates to be due to the combined effects of the altered physical conditions of the air—the increased moisture and temperature, in a stagnant atmosphere. The important subject of the composition, &c., of sewer air is inadequately discussed in eight lines.

Mr. Spence's suggestion that all the smoke of a city should be conducted by the sewers to a few enormous chimneys, where it could be completely burnt (p. 155), appears to be commended by the author. Certainly Sir B. W. Richardson proposed to adopt this method in his model city of Hygeia, but it is inconceivable that it could be efficiently applied. The various methods of freeing air from trade dusts and gases might have been included with advantage in such a work, and the volume seems incomplete without some reference to analytical methods—even if the reference were confined to the more simple practical tests for the more important gaseous impurities of the atmosphere of dwelling and working rooms.

But notwithstanding these deficiencies, the matter is, generally speaking, so well dealt with that the work may be confidently recommended for study and reference purposes.

The range of treatment embraces eighteen chapters. These deal with the composition of air; the discovery of the atmospheric gases; respiration; air-pressure in relation to life; the temperature, humidity, and thermolysis of air, and health; air and solar radiation; electricity and radio-activity, and their relation to climate; impure and polluted air; dust and germs; ventilation, draughts, and "colds"; artificial atmospheres; the open-air treatment of consumption; and open-air schools.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Natural History Museum.

IN reference to the article on the Natural History Museum in NATURE of January 20 (p. 343), in which Sir Archibald Geikie is represented as saying that the questions put to him in the letter from the Speaker of the House of Commons "were entirely in reference to the relations between the Trustees and the Museum," historical accuracy demands that it should be stated that the questions of Mr. Lowther were two in number (see NATURE, December 16, 1909, p. 196). They were:—(1) "Whether the Board of Trustees, acting through its Standing Committee, is in your judgment the best authority for the government of such an institution as the Natural History Departments of the British Museum?" and (2) "Whether, under the existing statutes and rules, the scientific management of the Natural History Museum suffers any detriment from its association with the Museum at Bloomsbury?"

It is clear that in his communication to you Sir Archibald Geikie has overlooked Mr. Lowther's second question, with which alone (so far as these two questions are concerned) the present agitation has concerned itself. We have always admitted that "a system of control by Trustees is the best" (see NATURE, December 30, 1909, p. 254). You were therefore quite right in your impression that the main point of contention was the complete separation of the governance and administration of the Natural History Museum from the other collections in the British Museum. Mr. Carruthers's letter does not touch the point at issue, except in so far as it seems to show that Prof. Huxley was in agreement with our view that "a system of control by Trustees is the best." He says nothing to show that Prof. Huxley came to disagree with the conclusion to which he had twice put his signature, once after a prolonged inquiry by Royal Commission, that it was of fundamental importance that the governance and administration of the two Museums should be separate.

A. SEDGWICK.

Markings on Mars as seen with Small and Large Telescopes.

THAT large telescopes are liable to less accurate definition of planetary markings than small ones can easily be verified in the following manner, and tested for any given occasion. The spurious disc and rings made of a star by a telescope is a real image, due to the interference of the light-waves—as real an image, although produced by a different cause, as that of a planet's disc with its markings. If atmosphere and glass be perfect, the image consists of a round disc, encircled by concentric and continuous rings of light. The only difference in the image with different apertures is that the larger the aperture the smaller the disc, and the closer and thinner the rings. If this image assume any other form, it is either because the objective is poor, which is commoner with objectives than is supposed, as Hartmann's tests have shown,[1] or because the seeing is defective. In proportion as the seeing is bad the rings of the image begin to waver, then break up into fragments, a sort of mosaic, and finally end in an indiscriminate assemblance of points. In certain kinds of bad seeing the parts may seem quite steady, but that the mosaic exists is proof positive of poor seeing.

Now this image as made by different apertures may be compared either by observing with different telescopes at the same place and time or by diaphragming down a large objective. When this is done it becomes at once evident that the smaller aperture always gives the more accurate definition of the optical disc and rings in spite of the theoretical greater resolvability of the larger glass. If, now, under the same conditions of seeing in which the rings appear continuous—their real form—in the smaller glass, the aperture be increased, the rings will be seen to break up into detached masses. It is very rare that they ever appear otherwise in a very large glass, for the seeing is almost never good enough thus to show them, accuracy of definition demanding much better air for a large than for a small aperture.

---

[1] The Lowell Observatory glass has been tested by this method, and proves to yield the best images of any yet examined. (Bulletin in preparation.)

Now what happens to the lines of the image of a star—for the rings are simply circular lines—must happen in the same manner to planetary lines. They too must break up into a mosaic in a large glass whenever the rings do. This shows that planetary lines would necessarily assume a mosaic in a large glass contrary to their true form of continuous linearity.

Percival Lowell.

Lowell Observatory, Flagstaff, Arizona.

Colour-blindness.

In the summary of the case of Mr. John Trattles published in Nature of January 27 the expression is used:—"Dr. Ettles, who had examined Mr. Trattles, and was of opinion that he was not colour-blind, was also present."

That is only relatively accurate, and it is in the reservation that the real point lies. I examined Mr. Trattles on May 10, 11, and 12 last year. His spectrum range included both B and H lines—actually, 0·75 μ in the red to 0·39 μ in the violet. His sense of colour was less good about 0·54 μ than in the rest of the spectrum. Indeed, it was what one might call "bad." It was the presence of this defect which caused him to give such contradictory replies at Sir Wm. Abney's examination. My certificate, which was read in the House of Lords by Lord Muskerry in the debate referred to, viz. June 30, 1909, expressly stated that Trattles was competent to navigate a ship. It did not state that his colour vision was in all respects perfect.

Sir Wm. Abney and those associated with him concluded that, as the result of their tests, Trattles was "completely red-blind." I saw in those tests simply a confirmation of my own conclusions. We were at one in the symptoms, but we strongly differ in the diagnosis. If the Board of Trade starboard light were a yellow-green, Trattles would be unfit; but it is a blue-green, and he sees it perfectly.

As to red, he is anything but scoterythrous; that is what comes of being obsessed with a colour-vision theory.

One other point, the "recondite test of simultaneous contrast colours" is very much open to criticism. A simultaneous colour contrast is not a "colour" in the ordinary sense; it possesses no dominant wave-length; it is an optical illusion. Is an optical illusion so accepted and clear a test that it may be used as a touchstone to determine whether a man's career shall be ruined or not?

William Ettles.

34 Wimpole Street, Cavendish Square, W.,
January 30.

We regret that we were in error in stating that Dr. Ettles was of opinion that Mr. Trattles was not colour-blind. It is interesting to know that he found the colour vision "less good" at a point in the spectrum not far removed from the region where the so-called "red-blind" person has a so-called "neutral band." The accurate determination of the spectrum range and of the deviations from the normal within that range constitutes the fundamental problem in discriminating colour-blindness. The accuracy of the determination, however, depends upon the methods adopted and the precision of the application of these methods.

With regard to the simultaneous contrast test, Dr. Ettles states that it is an optical illusion. If this be admitted, it is constant in its character in all normal individuals; hence any deviation may be fairly regarded as indicating a pathological condition of colour vision. As physiologists we cannot admit as a valid argument against the test that it is difficult or impossible satisfactorily to correlate the physical facts with the physiological manifestations.

But is it necessary or advisable that the divergence of opinion on the exact conditions of Mr. Trattles's colour vision should be further emphasised? The case has been adjudicated upon, and has amply demonstrated the need of reform either in the tests or in the application of the tests. The Board of Trade cannot, and ought not, to accept *any* risk of allowing a man with possibly dangerous defective colour vision to pass the examination. It is better that slight hardship should fall upon a few individuals than that many lives should be endangered; but the hardship must be minimised, and this object will be best attained by ensuring that the individuals shall be eliminated as early as possible in their careers. Hence it is of the utmost importance that the first examination shall be authoritative and conclusive.

The Writer of the Article.

Records of the Earthquake of January 22.

On January 22 the Kew Milne horizontal pendulum recorded a large earthquake, of which the preliminary tremors commenced at about 8h. 52·6m. a.m., and the large waves at about 8h. 56·1m. The limits of registration, 17 mm., were exceeded between 8h. 58m. and 8h. 59m., and again at 9h. 0·4m. Synchronous with both maxima there were burrs on the magnetic declination trace. The largest, which simulated an oscillation of 1·5′ in declination, commenced about 8h. 57m., and lasted about five minutes. The movements on the declination trace were unquestionably seismic in character, and represented the mechanical effect of the principal earth tremors. The horizontal and vertical force traces were not sensibly affected.

Charles Chree.

The National Physical Laboratory (Kew Observatory Department), Richmond, Surrey, January 27.

An Earthquake Phenomenon.

A curious phenomenon connected with the earthquake of January 22 was that the maximum movement was accompanied by a sudden tilt. The amount of this was approximately one second of arc, its direction being towards the north-west. This would correspond to a rise of the ground on the south-east. It took place at about 8 a.m., when the booms of five horizontal pendulums were suddenly displaced from their normal position. Those oriented east and west were swung to the north, whilst those at right angles moved to the west. Pendulums in rooms 80 yards apart were displaced similarly. From 12.45 they crept back somewhat intermittently towards their original position, which they reached about 4 p.m.

Whether this indicates a local change in the dip of the strata (chalk) on which my instruments are founded or a more extended change of level cannot be stated with any certainty. At Bidston a pendulum oriented east-west was displaced towards the north, and at West Bromwich a pair of pendulums swung more on one side of their normal position than on the other. Their behaviour suggested a displacement similar to that observed at Shide. Permanent changes in the ground near the origin of a large earthquake are common.

J. Milne.

Shide, Isle of Wight.

The Preparation of Silicon. A Warning.

A common method of preparing silicon is by mixing silica and magnesium powder in molecular proportions and heating until the following reaction takes place:—

$$SiO_2 + 2Mg = Si + 2MgO.$$

The majority of text-books recommend the use of silica in the form of silver sand or ground quartz, but they do not say it is absolutely necessary, or even desirable, that it should be in this form, and one well-known treatise states that precipitated silica and pure magnesium powder will yield very pure silicon. This authority adds that if the experiment is performed with precipitated silica the reaction is attended by a brilliant flash of light.

Having recently had occasion to prepare some silicon, precipitated silica was heated with magnesium powder in a Hessian crucible. One quarter gram-molecule of each was employed. The heating had proceeded some little time when suddenly the mixture exploded with terrific violence, shattering the crucible to a powder and sending out a great sheet of white flame. So great was the force of the explosion that the iron ring of the retort stand which held the crucible was bent out of shape. On examination it was found that the ingredients were pure, except that they might not have been quite free from moisture.

What I wish particularly to point out is that there is not a word in any of the text-books I have referred to of the danger of a very serious explosion in the above preparation.

Perhaps someone can say, definitely, whether the presence of a trace of water will cause such a mixture to explode on heating.

Intermittent Glow of the Tail of the New Comet.

In Mr. Rolston's interesting and valuable article on the new comet (Nature, January 27) reference is made to the statement of the Rev. F. J. Jervis-Smith that several persons observing at Lymington on January 22 thought the tail appeared to flash slightly and continuously.

Now, on the evening of that day I got the impression, on seeing the comet setting in the west-south-west, that there was an intermittent glow of the tail matter, in no very marked degree, it is true, but still there was a seeming perceptibility.

Later that evening I was told by an unskilled observer that he had seen "faint lights issue from the head and pass up to the end of the tail."

The conclusion I came to at the time exactly coincides with that referred to in the article, which is that the appearance was referable to the low position of the object and consequent atmospheric effects.

The interposition between the observer and the tail of a slight cloud or of some distant mass of smoke, though in itself too filmy to be noticed from afar off against a dark sky, would, doubtless, account for these light changes.

A correspondent once wrote to me—in some alarm, I thought—that Jupiter had on the previous evening behaved in a manner which was, to say the least, extraordinary, in that it had "kept going in and out" for five minutes on end. As the planet was then low in the sky, I concluded that the effect described by my perturbed correspondent was due to rapidly moving patches of unseen denser vapour than that which surrounded the planet, intruding in the line of sight. At the same time, I was far from being unmindful of the way in which Jupiter's light will frequently palpitate when the planet is nearing the horizon.

Unemployed Laboratory Assistants.

A number of lads who have been employed as laboratory monitors in secondary schools, and whom the London County Council are unable to retain in their service beyond the age of sixteen years, have been referred to us by the London County Council with the view of our placing them. Some of them we have already been able to place in suitable employment, but there are still one or two on our books for whom we seek situations.

They all have an elementary knowledge of physics and chemistry. Some have learned glass-blowing and bending, and one of the applicants has already passed the Board of Education examination in chemistry (Stage I.). If any readers of Nature would like to have further particulars of these boys, I should be glad to supply them with information.

THE AROLLA PINE.[1]

The Arve or Arolla pine is the most beautiful of Alpine conifers. The glossy green of its acicular tufted leaves, the curving cone of its outline, the combined strength and grace of its growth, make it yet more attractive in colour and in form than the darker and sturdier spruce. It ranges, though rather fitful and sporadic in distribution, throughout the Alpine chain, passing on to the Carpathians, where, however, it does not grow nearly so high above the sea-level, but it is most abundant in north-eastern Asia, which is apparently its birthplace. There it extends northward to the tree-limit, eastward to the Altai, the Sea of Okhotsk, and the north of Japan, and westward even so far as the Lower Dwina. Between the occupants of these two provinces some marked differences exist, so that Dr. Rikli recognises an Arctic and an Alpine subspecies, to the latter of which his memoir is restricted. The Arve is a lover of the mountains, and on these it has a rather wide vertical range. When growing wild it is seldom met with below the 1350-metre contour-line. Dr. Rikli mentions as the lowest instance one at about 1200, near Raron, in the Upper Rhone valley. Its upper limit is about 2400 metres, the highest occurrence on record being 2585 metres, on the Plattje, near Saas Fee. Such cases, however, are exceptional, where the tree obviously has had a hard struggle for existence, and it cannot be said to flourish above 2300 metres. On the Northern range of the Alps, the vertical limits within which it grows freely are narrower than in the Central—or Pennine and Lepontine—range, the difference between them, in

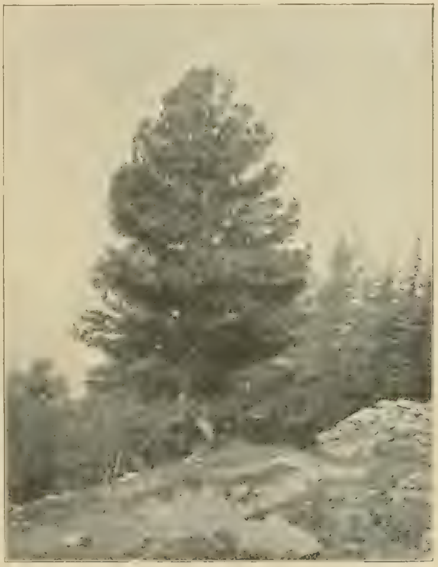

Fig. 1.—The Arve in Youth.

---

[1] Die Arve in der Schweiz. Ein Beitrag zur Waldgeschichte und Waldwirtschaft der Schweizer Alpen von Dr. M. Rikli. Mit einer Arvenkarte der Schweiz, einer Waldkarte von Davos, 19 Specialkarten in Lithographie, 9 Tafeln in Lichtdruck und 51 Textbildern. (Neue Denkschriften der Schweizerischen Naturforschenden Gesellschaft, Band xliv.) Pp. xl+455. (Basel: Georg & Cie.; Zürich: Zürcher & Furrer, 1909.)

Canton Valais, being 1385 metres, and in Canton St. Gall only 270 metres.

Sometimes these pines form distinct and close-grown woods, to the exclusion of other conifers, in which each one is similarly developed. Such woods, however, are not common, and are generally restricted to the Grisons and Canton Valais, where the Arve is most abundant. More often, however, even when not mixed with other kinds, individuals grow either in more open order or in small clusters, or even as solitaries. On the slopes of the northern Alps they not unfrequently form trailing lines, the trees in which, as might be expected, often bear the marks of storm and stress. But the Arve more commonly is associated with other conifers—the larch, the spruce, the Scotch fir, and sometimes the silver fir. Another, but more lowly companion, is the Legföhre (*Pinus montana*), that trailing conifer which is more abundant in the eastern than in the western Alps, and altogether absent, so far as Dr. Rikli knows, from the Valais and the Oberland. The Arve also grows in company with other trees and bushes, such as the birch, the beech, the Alpine alder, a service (*Sorbus aucuparia*), and, of course, with the common rhododendron (*R. ferrugineum*), the bearberry (*Arctostaphylos uvaursi*), the bilberry (*Vaccinium myrtillus*), and another member of that genus; while in the associated flora a mid-Europe Alpine, a north-Europe Alpine, and an Arctic-Altaian element may be detected; the last, as Dr. Rikli remarks, forming a link with the Arve's original home.

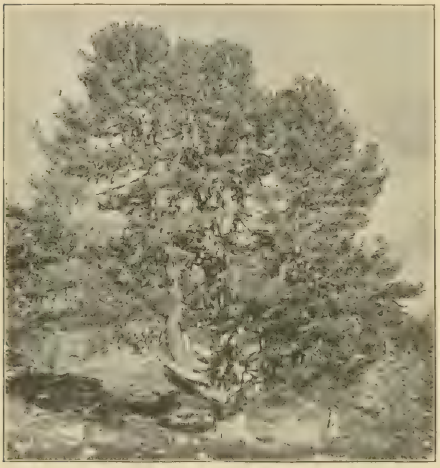

FIG. 2.—The Arve in Age.

This memoir describes, with illustrations from reproduced photographs, the modes of growth which, according to circumstances, the Arve exhibits. A solitary one, when in its full vigour, is a happy combination, as Fig. 1 proves, of beauty and strength. With the advance of age it is apt to lose its symmetry and compactness, though it is still, as Fig. 2 shows, an ornament to the landscape. No more than other trees does it escape being torn by the storm or the avalanche, shattered by the lightning, and nipped, especially when young, by exceptionally severe frosts; but when overthrown, it sometimes puts out new roots and converts side branches into leading stems. But the Arve has its enemies also among other living things. Man is responsible for reckless hacking and felling, for forest fires or damage done in climbing after its cones, the kernels in which have a nut-like flavour. But now that he is restrained by forest laws, other creatures are the more formidable. Goats, sheep, and cattle (especially the first, if carelessly tended) do much damage to the young plants; the roe-deer, the stag, and the chamois take their share when in search of food. The marten, the squirrel, and even the fox, feed on the nuts, though the last, like the wood and hazel mice, must wait until they have fallen. Some birds also have similar tastes. Most conspicuous among these is the nutcracker (*Nucifraga caryocatactes*), which is never so common in the Alps as where the Arve is plentiful and its fruit is ripening. The capercaillie (*Tetrao urogallus*) feeds on the young shoots, and the common sparrow, generally to the front in mischief, has been known to do the same with seedlings. Its insect foes we can only mention.

In short, Dr. Rikli seems to have touched on every point of interest in the life-history of *Pinus cembra* in Switzerland, and has done his work with Teutonic thoroughness. He goes over the country, canton by canton, and valley by valley, citing statistics of the numbers of the trees, their distribution on either slope, and other distinctive features; he gives many particulars of the age, size, and rate of growth of the older trees, and refers to the care which, of late years, has been bestowed on their culture. The maps appended to the volume are interesting as showing the relative abundance or scarcity of *Pinus cembra* in different districts of the Alps, and the numerous photographs, especially the eighteen separately printed, some of which are unusually good, recall to lovers of that mountain chain pleasant memories of this handsome tree. To such Dr. Rikli's work will always be attractive; but to students of forestry it will be indispensable. T. G. B.

ON HALLEY'S COMET AS SEEN FROM THE EARTH.

THE following table gives ecliptic coordinates of Halley's comet to two decimal places at intervals of four days through an arc extending from one end to the other of the *latus rectum* of its orbit. The zero of time is very nearly the moment of perihelion passage, and the figures apply approximately to any return.

Day	x	y	z	Day	x	y	z
−52	+0·95	+0·73	+0·12	+4	+0·21	−0·54	+0·15
−48	+0·93	+0·64	+0·13	+8	+0·10	−0·59	+0·13
−44	+0·91	+0·55	+0·14	+12	−0·02	−0·64	+0·11
−40	+0·89	+0·46	+0·15	+16	−0·13	−0·67	+0·09
−36	+0·86	+0·37	+0·16	+20	−0·24	−0·69	+0·06
−32	+0·83	+0·27	+0·17	+24	−0·34	−0·70	+0·04
−28	+0·80	+0·18	+0·18	+28	−0·45	−0·71	+0·01
−24	+0·75	+0·08	+0·18	+32	0·55	−0·71	−0·02
−20	+0·70	−0·02	+0·19	+36	−0·64	−0·70	−0·04
−16	+0·65	−0·12	+0·19	+40	−0·74	−0·70	−0·07
−12	+0·58	−0·21	+0·19	+44	−0·83	−0·68	−0·09
−8	+0·50	−0·31	+0·19	+48	−0·91	−0·67	−0·12
−4	+0·41	−0·39	+0·18	+52	−1·00	−0·65	−0·14
0	+0·31	−0·47	+0·17				

The comet attains unit distance from the sun thirty-nine days before and after perihelion passage. On the former occasion its z coordinate perpendicular to the ecliptic is +0·15, on the latter −0·07. It is evident, therefore, that the closest possible approach to the earth will occur after perihelion passage. The heliocentric longitude is 30° on the earlier occasion and 225° on the later. The earth reaches these heliocentric longitudes in October and May respectively.

At the return of 1835 perihelion passage was on November 16. There was consequently a close approach between the earth and the comet about a month earlier. In 1910 the perihelion passage will be on April 20; a month earlier than this, when the comet is close to the earth's orbit, the earth will be at the diametrically opposite point. A month after perihelion, however, there will be a very close approach.

The most unfortunate date for perihelion passage for yielding a close approach to the earth is January. The comet would then be behind the sun at perihelion, and more than an astronomical unit away when crossing the earth's orbit.

On the present return the approach after perihelion will be unusually close. The following table gives the ecliptic coordinates of the earth for the annexed dates:—

Date		x		y
1910, May 10	...	−0·65	. .	−0·76
,, 14	...	−0·60	. .	−0·80
,, 18	.	−0·55	...	−0·84
,, 22	...	−0·49	...	−0·87
,, 26	...	−0·43	...	−0·90
,, 30	...	−0·37	...	−0·93

When, therefore, the comet crosses the plane of the ecliptic twenty-eight days after perihelion passage (May 18) it will be almost exactly between the earth and the sun, and the earth will probably be in the tail of the comet.

The closest approach at this return takes place a day or two later.

The closest approach possible would correspond to a perihelion passage about a week and a half earlier in the year than the present one.

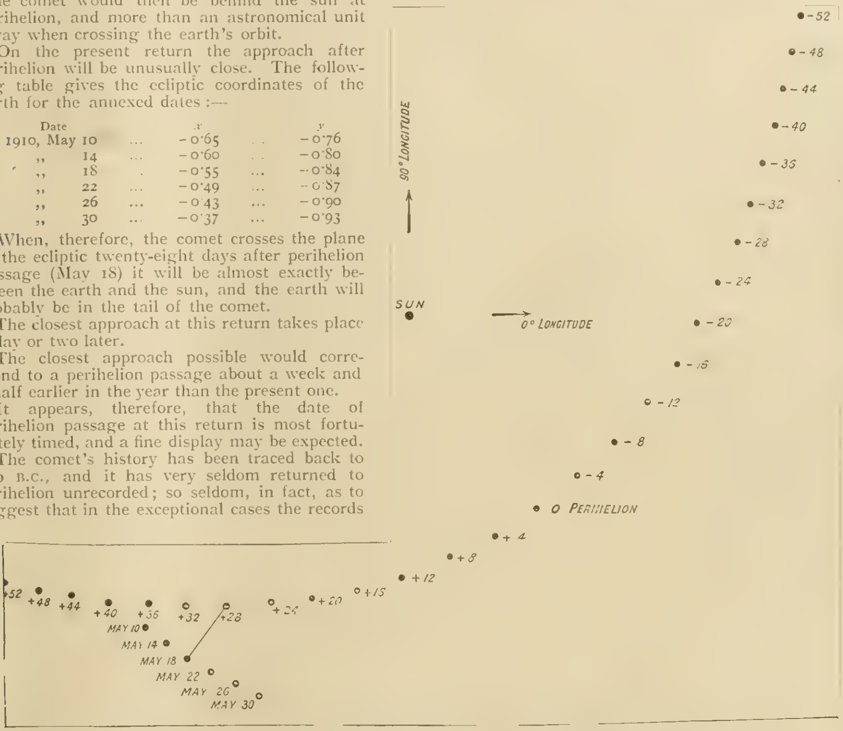
It appears, therefore, that the date of perihelion passage at this return is most fortunately timed, and a fine display may be expected.

The comet's history has been traced back to 240 B.C., and it has very seldom returned to perihelion unrecorded; so seldom, in fact, as to suggest that in the exceptional cases the records have perished rather than that the comet in any circumstances can pass by unseen.

A tail twenty or thirty degrees in length is expected on the present occasion. It will be best seen at the end of May, and in England it will, unfortunately, be lower in the sky than in more southern latitudes. There will, however, be no difficulty whatever in seeing it in England, unless there is a prolonged spell of bad weather.

The approach to the earth is so close that an American astronomer has conceived the idea of weighing the comet by the deviation it produces in the orbit of the earth. We can hardly believe that the effect produced will be one-thousandth part of the least measurable quantity, but the speculation is most interesting in view of the fact that there are unexplained phenomena in planetary movements.

P. H. Cowell.



The diagram gives the position of the Earth for six days in May; also the position of the comet on twenty-seven dates measured from perihelion passage in days. The line of sight is drawn for May 18, twenty-eight days after perihelion, when the comet transits across the Sun.

JUBILEE OF THE THEORY OF ELECTROLYTIC DISSOCIATION.[1]

In his address to the British Association in 1884, the president, Lord Rayleigh, said, "from the further study of electrolysis we may expect to gain improved views as to the nature of chemical reactions, and of the forces concerned in bringing them about. . . . I cannot help thinking that the next great advance, of which we have already seen some foreshadowing, will come on this side."

The first step of the advance spoken of by Lord Rayleigh had already been made, for in that same year the young Swedish physicist, Arrhenius, presented as his doctor's dissertation to the University of Upsala a memoir with the title "Recherches sur la Conductibilité galvanique des Électrolytes. Première Partie: La Conductibilité des Solutions aqueuses extrêmement diluées," which was published in the "Bihang till Kongl. Vetenskapsakademiens Handlingar," vol. viii., and was followed in the same year by the second part, entitled "Théorie chimique des Électrolytes." These researches contain the germ of the theory of electrolytic dissociation, which, however, only received its complete statement in 1887, in the first volume of the newly founded *Zeitschrift für physikalische Chemie.*

---

[1] *Zeitschrift für physikalische Chemie.* Bd. 69, Jubelband. Svante Arrhenius zur Feier des 25-jährigen Bestandes seiner Theorie der elektrolytischen Dissociation gewidmet von seinen Freunden und Schülern. Mit einer Einleitung von W. Ostwald. Pp. xxix+685. (Leipzig: W. Engelmann, 1909.)

The impression made on the university authorities by Arrhenius's thesis was not favourable. In their view, apparently, it was neither very good chemistry nor very good physics, and only deserved the mild commendation "non sine laude approbatur." Indeed, the fundamental conceptions of the new theory were so much at variance with the current ideas of both physicists and chemists that it can scarcely excite wonder to find that a strenuous opposition was offered to the introduction of the notion of free ions into science. Had it not been for the warm advocacy of Ostwald, who was already a power in the domain of physical chemistry, it is not at all unlikely that the theory would have remained in abeyance (as did Avogadro's hypothesis for nearly fifty years) until the necessity for it became imperative.

Happily, however, for the progress of science, the appearance of the theory synchronised with that of van 't Hoff's theory of osmotic pressure, which it supplemented by accounting for the apparent abnormalities displayed by electrolytic solutions. Armed with these two powerful weapons, Ostwald, by his writings, by his researches, and not least by his establishment of a school of physical chemistry in Leipzig, where, under his stimulus, the theories were practically applied by his pupils to the elucidation of numerous problems in the physics and chemistry of solutions, gradually overcame effective opposition, and secured a permanent, if somewhat reluctant, recognition of the new ideas. To this period belongs the fundamental application of the two theories by Nernst to the calculation of electromotive forces. The only parallel in physical chemistry to the activity and fertility of those days is to be found in the contemporary development of radio-active research.

We occasionally hear it said at the present time that the theory of electrolytic dissociation is "played out," that it was useful for a season, but that it must now be superseded by something different and better. Not many years ago, similar statements were made regarding the kinetic theory of gases—that it had served its purpose, was very good so far as it went, and might be peacefully left to die a natural death. To-day the kinetic theory is far from moribund, and it seems to the present writer that a corresponding vitality is inherent in the theory of Arrhenius. Wide-reaching and fruitful physical theories generally contain a well-defined notion which survives any change of form which the theory or its mechanical interpretation may undergo. Dalton's atomic theory contains the imperishable notion of fixed combining weights for the elements; Avogadro's theory contains the definition of molecular weight; and from these two together we obtain, as Cannizzaro showed, the modern atomic weight. Whether we believe in atoms and molecules or not, these conceptions of combining, atomic and molecular weights will persist unaltered, and survive any upheaval in chemical theory. Similarly, Arrhenius's great positive contribution to physico-chemical science is the notion and practical definition of degree of ionisation. Whatever be our views of the origin and nature of ions, we must, in any quantitative investigation of the properties of electrolytic solutions, have recourse to the notion of degree of ionisation.

Arrhenius has since been active in many fields besides that of physical chemistry, notably in cosmic physics and in serum-therapy, bringing to bear in these branches of science the same clear-headedness and sublimated common-sense which enable him in the multiplicity of the details he so easily masters to detect the simple principles which coordinate and govern the whole. The present volume, however, the sixty-ninth of the journal which in its first volume contained the statement of his theory, is only concerned with his physico-chemical work, and is the first of two volumes written in his honour by pupils and friends to signalise the completion of the fiftieth year of his age and the twenty-fifth of his theory. To it physical chemists in all parts of the world have contributed, testifying to the universal esteem in which Arrhenius and his work are held, and a fitting introduction is written by Ostwald, who relates the early history and development of the theory with many pleasant biographical and autobiographical details.

JAMES WALKER.

PROF. F. W. KOHLRAUSCH.

It is with great regret that we have to record the death of the eminent physicist, Prof. F. W. Kohlrausch.

Kohlrausch was born in October, 1840, at Rinteln on the Weser. His father, Rudolph Kohlrausch (1809–1858), was a physicist of great distinction who, in conjunction with Wilhelm Weber, carried out for the first time a determination of the ratio of the electromagnetic to the electrostatic unit of electric quantity, and thus laid one of the corner-stones of the absolute system of electrical measurement. It was, therefore, natural that the son's attention should be early directed towards physical science. He studied at Göttingen and Erlangen, graduated Ph.D. in 1863, and in 1866 was appointed Professor Extraordinarius at Göttingen. After about a year as professor of physics at the School of Technology at Frankfort-on-the-Main, he was appointed, in 1871, to a similar post at the Grand-ducal Polytechnic at Darmstadt. In 1875 he became professor of physics in the University of Wurzburg, and was transferred thence to Strassburg in 1888. He was appointed president of the Physikalisch-Technische Reichsanstalt at Charlottenburg in 1895, and, in the same year, was elected a member of the Academy of Science of Berlin and also a Foreign Member of the Royal Society of London. He was made honorary professor of physics in the University of Berlin in 1900. He resigned his post at Charlottenburg in 1905. He was elected an honorary member of the Physical Society of London in 1906. He died at Marburg in January of this year.

Kohlrausch was the author of a great number of papers giving the results of experimental investigations in many branches of physics, but the subjects which chiefly occupied him were the methods of measuring magnetic and electrical quantities. Among his contributions to this branch of science we may mention his method for the absolute measurement of the horizontal component of the earth's magnetic field and of the strength of an electric current, by simultaneous observations of the deflection of the needle of a tangent-galvanometer and of a suspended coil where both instruments are traversed by the same current. Another important set of experiments, published in 1874, had for its object the determination of the absolute value of the "Siemens unit" of electrical resistance. The result which Kohlrausch arrived at, though afterwards shown to be appreciably in error, was of considerable importance historically, since it directed attention to the necessity of examining further the result obtained in 1863 and 1864 by Maxwell and his coadjutors for the British Association Committee on Electrical Standards.

In 1871 Kohlrausch introduced a method for measuring the electrical resistance of electrolytes founded upon the employment of alternating currents generated by the revolution of a magnet inside a coil of wire, the relative positions of magnet and coil being like those in an ordinary galvanometer. In this way the disturbing effect due to the polarisation of the electrodes was in a great measure, if not entirely, got rid of, and the results obtained were a great advance in respect of accuracy upon those previously obtained. In later modifications of the method the alternate currents of an induction-coil were used. This investigation formed the starting point of a long series of researches into the conducting power of electrolytic solutions. The examination of a great number of soluble salts in aqueous solutions of different concentrations showed that, although the conductivity decreases with decreasing concentration, the ratio of conductivity to concentration increases, at first nearly uniformly, but approaches a definite limit for each salt when very small concentrations are reached, that is, when the solutions are very dilute. It was further found that, when the proportion of salt in solution was expressed in terms of the equivalent mass of the salt, the limiting (maximum) value of the above ratio varied within comparatively narrow limits for a great number of salts. Another important result of Kohlrausch's experiments was the establishment of a simple relation between the conductivities of dilute solutions and the mobilities, as deduced from Hittorf's measurements, of the ions into which the respective salts may be supposed to be broken up when dissolved.

Kohlrausch rendered an extremely valuable service to the teaching of experimental physics by the publication, in 1870, of his "Leitfaden der praktischen Physik." This was the first, and, in the writer's opinion, the best of numerous works of the same kind that have since appeared in various countries, designed to guide students of physics in a systematic course of practical work in the physical laboratory. The high appreciation it has met with is shown by the number of editions that have been called for—it reached the eighth in 1896; it was translated into English by Messrs. T. H. Waller and H. R. Procter soon after its first appearance, and a second English edition was published in 1883.

G. C. F.

SIR CHARLES TODD, K.C.M.G., F.R.S.

Few men have lived a fuller life or given more freely of their best than Sir Charles Todd, whose death we deeply regret to record. It is only about three years ago that he retired from active service, but he was then above eighty years of age and his career had been unusually long. His scientific life dates back to 1841, when he entered the Royal Observatory, Greenwich. The instruments, as those who used them, have passed away, and he must have been the last survivor of the little band who worked with the old meridian transit and circle. There he acquired a training in scientific methods which he was destined to turn to such useful account in promoting the interests of a new colony. In South Australia he found his work, and there his memory will be treasured. For it was his fortune to organise two departments, the Post Office and the Meteorological Service, which have contributed in no small degree to the growth of that thriving settlement.

It is not given to many to see their exertions and plans so speedily and completely successful as did Sir Charles Todd, or to fill simultaneously the three important positions of Postmaster-General, Superintendent of Telegraphs, and Government Astronomer. But it will be admitted that he filled this trinity of offices with credit to himself and to the advantage of others. The Post Office was practically his own organisation, which, continually growing with the requirements of the Colony, proved itself equal to the increasing demands. It was in connection with the establishment of the Telegraph Service, and its growing needs, that he made that remarkable ride of 2000 miles across the arid interior of the continent of Australia, from Adelaide to Port Darwen. The energy and intrepidity of the man were well illustrated by this memorable venture. No wonder that he loved to tell of that day, when he sat on the ground near Mount Stewart, amid uncomfortable surroundings, but forgot all in the sense of successful achievement, when, with a little pocket relay, he connected the wires and held communication with the extreme north and south of the island.

As Government Astronomer, it will be remembered that Sir Charles Todd took part in organising the expeditions for the observation of the transit of Venus, that he kept the 8-inch refractor steadily at work, and did what lay in his power to maintain an interest in astronomy. Still greater was the service he rendered in promoting a meteorological and climatological servey—so necessary in a new country, where the climatic conditions are of vital importance to the incoming settler. For something like forty years he maintained the meteorological service, and has left to his successor a complete and well-equipped organisation.

His talents were admirably fitted for the field in which they found scope. He knew how to inspire others with the tireless energy that carried him through so many difficulties; his geniality secured him many friends and willing workers that enabled him to accomplish so much; his life and history are written in the progress of the colony during the last fifty years. Amid the regrets of those among whom he laboured so well and so long, he will be remembered as one whose services gained the approval of his sovereign and the cordial appreciation of his scientific colleagues, and especially as a typical specimen of that class which, great in resolve as in achievement, has given strength and impulse to our Colonial Empire.

NOTES.

At the meeting of the Paris Academy of Sciences on January 24 Lord Rayleigh was elected a foreign associate member in succession to the late Prof. Simon Newcomb. Lord Rayleigh was elected a correspondant of the academy in 1890.

M. Emmanuel de Margerie has been elected president for 1910 of the Paris Geographical Society, and M. H. Deslandres and Colonel Bourgeois vice-presidents.

During his recent visit to St. Petersburg, Sir Ernest Shackleton was presented with the Constantine gold medal of the Russian Geographical Society.

The Lettsomian lectures on "The Cerebellum and its Affections" will be delivered by Dr. J. S. Risien Russell at the Medical Society of London on February 7 and 21 and March 7.

At the close of a public lecture by Dr. Sven Hedin in Rome on January 30, the King of Italy handed to him the large gold medal which has been conferred upon him by the Italian Geographical Society.

PROF. J. ARTHUR THOMSON has been elected president of the Royal Microscopical Society for the ensuing year.

WE regret to see the announcement of the death, on January 28, at seventy years of age, of Prof. F. Purser, professor of natural philosophy in the University of Dublin and the author of several notable works on Bessel's functions.

THE following officers have been elected for 1910 by the French Physical Society:—*President*, M. L. E. Bertin; *vice-president*, M. Lucien Poincaré; *general secretary*, M. H. Abraham; and *assistant secretary*, M. Jean Becquerel.

THE *Times* states that the Belgian expedition which will leave shortly for the Congo to make investigations in connection with sleeping sickness will be in charge of Dr. Rhodain, professor of bacteriology at the University of Louvain. Work will be begun in the northern part of the Katanga district.

THE president of the Royal College of Physicians has appointed Dr. H. B. Donkin to be the next Harveian orator, and Dr. G. N. Pitt to deliver the Bradshaw lecture. The Milroy lectures are to be delivered by Mr. A. G. R. Foulerton, on February 17, 22, and 24; the Goulstonian lectures by Dr. J. S. Bolton, on March 1, 3, and 8; and the Lumleian lectures by Prof. W. Osler, F.R.S., on March 10, 15, and 17.

WITH the object of giving still greater publicity to the advantages of intensive cultivation an exhibition of "French Gardening" is to be held at the Royal Botanical Society's Gardens at Regent's Park. Active preparations are now in progress for exhibiting and demonstrating every aspect of the close and scientific cultivation of the soil. The exhibition will take place in July, though the exact date is not yet definitely settled.

WE learn from the *Revue générale des Sciences* of January 15 that the French Guild of Jewellers is desirous of having the artificial "rubies" branded as *imitations*, like paste copies. Dr. Olivier, the editor of our contemporary, protests strongly against such action being taken by the Minister of Commerce, seeing that in composition and properties the natural and artificial materials are identical.

THE death is announced of Dr. J. Volhard, professor of chemistry in the University of Halle, at seventy-five years of age. For several years Dr. Volhard acted as Liebig's assistant, and ultimately was entrusted by him with the delivery of the course of lectures on organic chemistry which he regularly gave during the summer semester. His biography of Liebig, published last year, is a valuable and complete record of the life and work of that great chemist.

ON Tuesday next, February 8, Prof. F. W. Mott will begin a course of six lectures at the Royal Institution on "The Emotions and their Expression," and on Saturday, February 12, Sir J. J. Thomson will commence a course of six lectures on "Electric Waves and the Electromagnetic Theory of Light." The Friday evening discourse on February 11 will be delivered by Mr. C. E. S. Phillips, on "Electrical and other Properties of Sand," and on February 18 by Prof. H. H. Turner, on "Halley's Comet."

WE have received a letter signed by Lieut.-Colonel H. W. L. Hime, Sir G. Greenhill, and Mr. Oscar Guttmann, pointing out that at present there is no memorial of the foremost man of science of the thirteenth century, Roger Bacon, who foreshadowed many of the discoveries of modern science, and is known universally as the inventor of gunpowder. Contributions (however small) towards the erection of a memorial, in a suitable place, of this great Englishman may be sent to Mr. Oscar Guttmann, 60 Mark Lane, E.C.

THE executive committee of the National Physical Laboratory, on the nomination of the advisory committee for the national experimental tank, has appointed Mr. G. S. Baker to the post of superintendent of the tank, the funds for which have been provided by the generosity of Mr. A. F. Yarrow. After a distinguished career at the Royal Naval College, Greenwich, Mr. Baker was in November, 1900, appointed an assistant constructor in the Royal Corps of Naval Constructors. He served four years as assistant to Mr. R. E. Froude, F.R.S., at the Admiralty Experiment Works, and two and a half years as professional secretary to the Director of Naval Construction, and has also had experience in the general design work of the Admiralty Office. Thus he goes to the laboratory with distinguished qualifications, and on the strong recommendation of those who have the best grounds for estimating the value of his previous work.

THE permanent committee of the International Congress of Photography is arranging to hold the fifth International Congress in Brussels early next August, or about that time. The primary object of these congresses is to reduce, as far as possible, the confusing and often inconvenient variations that occur in nomenclature, definitions, standards, &c. Promises of support have been received for the coming congress from all parts of the world, and arrangements are being made for the presentation of reports by specialists on recent progress and the present state of knowledge in many of the branches of photographic work. It is hoped that England will take a full share in the congress. A complete programme will be issued as soon as possible. The membership subscription is ten francs or eight shillings, which entitles the member to a copy of the report of the proceedings. Inquiries may be addressed to either of the honorary general secretaries, M. Ch. Puttemans, 1 Palais du Midi, Brussels, or M. L.-P. Clerc, 52 Boulevard Saint Jacques, Paris XIV.; but for the convenience of English members inquiries and subscriptions may be sent to Mr. Chapman Jones, 11 Eaton Rise, Ealing, London, W.

BY the courtesy of the director of the Meteorological Office, the advisory committee for aëronautics is able to announce that a selection of current autographic records of wind velocity from the twenty-three anemograph stations in connection with the office, and other meteorological documents of interest to aëronauts, will be available for inspection at the Meteorological Office daily from 10 a.m. to 4 p.m. (Saturdays, 1 p.m.). The structure of wind and the changes to which it is liable are of great practical importance in aëronautical work. The association of changes in velocity with changes in direction, which are sometimes quite sudden, make aëronautical work especially difficult. There is sufficient information now available to indicate the conditions in which such changes may be expected. The anemographic records are selected to show good examples of the different kinds of wind structure recorded at the anemograph stations in these islands and to illustrate the changes that take place. The phenomena on any selected occasion can be compared with records from barographs or other self-recording instruments, or with the conditions indicated on the daily charts. The exhibits also include the summaries, which are not published, of the wind tabulations for all the anemometers in connection with the office from 1906 to 1909 inclusive. There is, besides, a series of diagrams representing the variation of wind velocity with height for all the kite ascents reported to the office in 1908 and 1909. These diagrams show a remarkable approximation, on many occasions, to direct proportionality between height above sea-level and the wind velocity in the upper air, irrespective of the height of the station at which the observation is made, and suggest a working practical rule for computing the increase of wind aloft. Opportunity is also afforded for considering the computation of gradient wind which must form the basis of any satisfactory method of dealing with wind measurements.

THE Paris floods have fortunately passed their maximum height, and are now generally subsiding. The information to hand having a bearing on the direct cause of the flood is exceedingly meagre, and until the detailed report of the Service hydrométrique is available little can be said. The data collected by this service is very complete, and extends over a period of fifty years. A series of low barometric systems passed over the northern portion of the Mediterranean and the south of France after January 19, and these occasioned exceptionally heavy rains in the catchment basin of the river and its tributaries. In Paris the aggregate rainfall from January 17 to January 25 was 2·08 inches, but this is quite inadequate to occasion the tremendous rise of the Seine which occurred; on no day did the rainfall amount to 0·5 inch. The rains were heavier near the source of the river, and in parts of France and Switzerland the rainfall for the two days January 18–19 amounted to fully 3 inches. According to the *Bulletin International* of the Central Meteorological Office of France, a swelling of the Seine was forecasted for January 20, but so late as January 20 the flood was not expected to exceed about 13 feet on January 22, and on January 21 this estimate was increased to 16 feet for January 23. On this date the estimate was further increased to 22 feet for January 24, and on January 25 the estimate for the increase was to 25 feet on January 26. At 8 a.m. on this date the actual flood reached 24·6 feet at Pont d'Austerlitz, 24 feet at Pont de la Tournelle, and 27 feet at Pont Royal, whilst a further slight increase was anticipated. The flood is said to have attained its maximum height on January 27–28, when it is reported as having reached 30 feet at Pont Royal. This is apparently higher than any previous record, exceeding that of 1764.

IT is with regret that we announce the death, in his sixtieth year, of Prof. W. Hillhouse, who held the chair of botany and vegetable physiology in Mason College and the University of Birmingham from 1882, when the chair was founded, until last year, when he was compelled by ill health to resign his appointment. Prof. Hillhouse was born at Bedford in 1850, and some of the earliest of his botanical work was in connection with the flora of his native county. He became a scholar of Trinity College, Cambridge, and afterwards a lecturer in that University. He was also keeper of the University herbarium. His life at Cambridge was marked by the birth of the *Cambridge Review*, of which he was one of the founders, and the editing of which he shared with Prof. Arnold and Vice-Principal Dale. He was widely known in the Birmingham district for his interest in educational matters, and in particular his efforts were directed to the establishment of a university extension movement in connection with Birmingham. He was a most energetic worker as honorary director of the Edgbaston Botanical Gardens, and was chairman of the council of the Midland Reafforesting Association. He was for a number of years on the Leicestershire Education Committee, and on retiring in 1909 received a very warm tribute for the services he had rendered in promoting the higher education of the county. One of his latest works on behalf of the University was the direction of the preliminary laying out of the ornamental grounds surrounding the new buildings at Edgbaston. His death will be sincerely regretted by his colleagues and by many of his old students, by whom his genial and kindly personality was much appreciated.

THE Victoria Museum of Launceston, Tasmania, is setting an example to other institutions of a like nature in arranging for the preparation of a series of dissected skeletons of native birds preserved in formalin. Of one of these a descriptive account has been published in the shape of a pamphlet, by Mr. H. H. Scott, the curator, under the title of "A Memoir on the Wedge-tailed Eagle, *Uroaëtus audax*; a Study in Avian Osteology."

ACCORDING to vol. ii. of the Journal of the Ipswich and District Field Club, the local excursions have been well attended during the past season, and have attracted a large amount of interest. Specially noteworthy is the discovery of a new Pleistocene bone-bed in a railway-cutting near the city. In connection with another "find" of mammalian remains may be noticed a repetition of the common error of giving *Cervus elephas* as the name of the red deer. The issue concludes with a reprint of a paper, by Dr. Bather, on crinoid remains from the Red Crag.

THE hairy-nosed wombat, *Phascolomys latifrons*, has hitherto been regarded as peculiar to South Australia. It appears, however, that in the Melbourne Museum are preserved four specimens of this species obtained from a lonely part of New South Wales in or near Denison country so long ago as the year 1884. Whether the species still survives there is unknown, but the donor of the specimens stated that it never occurred in any other part of the colony. These New South Wales hairy-nosed wombats are stated to differ from their relatives in the south in the characters of the nose, while the skull appeared to be shorter and rounder. If these differences are well established, the New South Wales form apparently indicates a distinct species.

IN an article on the menageries of the ancients and the Middle Ages and their influence on modern zoology, published in the January number of *La Revue des Idées*, Mr. Gustave Loisel directs attention to the circumstance that in ancient times Indians, Persians, Chaldeans, and Assyrians appear to have completely tamed the larger felines, carrying out this taming process to a considerably greater extent than is accomplished in the case of the hunting-leopard by the natives of modern India. They tamed the lion, for instance, to such a degree that it could be led in a halter and employed in the chase of deer, wild bulls, boars, and asses. It is also considered that the Chinese were the first to domesticate house-cats, and likewise to train cormorants for fishing.

IN an article on Miocene trees, published in the January number of the *American Naturalist*, Prof. T. D. A. Cockerell points out the remarkable resemblance between the fossil trees of the Florissant beds of Colorado and those of Œningen, in Baden. Out of six species selected from each locality, two are common to both sets of strata, while four are representative of each other. Nine other Florissant trees are quoted as being represented by allied forms at the present day, although in no instance is there specific identity, and it is noteworthy that some of the Florissant generic types are now restricted to Asia. Regarding the Œningen beds as of Upper Miocene age, the author considers that the Florissant deposits should be assigned to the same epoch.

To the January number of the *Zoologist* Prof. McIntosh contributes an article on the red or precious coral, in which he traces the evolution of our knowledge of this product from ancient times. Red coral was well known to the Romans, and about the beginning of the Christian era was exported in such quantities to India that it was difficult to obtain in the countries where it was produced. After describing the nature of the organism, and then giving a sketch of the mode of fishing, Prof. McIntosh states that the great bulk of the coral is sold at Messina, Naples, Genoa, Leghorn, and Marseilles, while the product of the Algerian fishery goes to Pisa and Trapani. About 160 tons of coral are brought yearly into Italy, the articles made from which are valued at nearly 500,000*l*. The total annual value of rough coral has been estimated at 2,000,000*l*., while after manufacture the value is stated to reach no less than 10,000,000*l*. The finest quality is of a delicate pinkish or flesh-like colour, uniform in tint throughout, and occurring in large pieces. Inferior samples are sold at 2*l*. per ounce, and small fragments, used for children's necklaces, at 5*s*. an ounce. Even worm-eaten coral has a value in the East, as the natives of certain districts believe that gods dwell in the holes.

DR. VICTOR WIDAKOWICH contributes an important memoir on the inversion of the germ-layers ("Entypie") in mammals to the *Zeitschrift für wissenschaftliche Zoologie* (vol. xciv., part ii.). The memoir is very beautifully illustrated, and the drawings of models of various stages in the early development of the rat should be extremely useful to students of this difficult subject.

IN the *Zeitschrift für wissenschaftliche Zoologie* (vol. xciv., part i.), Prof. B. Bachmetjew makes a very ingenious application of biometrical methods to the solution of the difficult problem of parthenogenesis and sex-determination in bees. From an elaborate statistical study of the variation in the number of hooks on the front margins of the hind wings, he finds that the resulting curves show either one or two maxima of frequency. He maintains that fertilisation of the eggs determines two maxima and parthenogenesis one. Thus queens always show two maxima of frequency in each hind wing; they are produced from fertilised eggs. Drones produced by workers show only a single maximum; they are produced from unfertilised eggs. With regard to sex-determination in bees, he adopts the preformation theory of Schultze and Lenhossék, but with the addition that drones may develop from unfertilised "female" eggs, and that the fertilisation of "male" eggs does not prevent the development from them of drones. He finds that one-year-old queens produce drones from unfertilised eggs—this appears to be the normal method. Queens of two or three years produce drones partly from unfertilised and partly from fertilised eggs, because, with advancing age, the closing mechanism of the seminal reservoir no longer works properly, and some of the drone eggs get fertilised, as it were, accidentally. Queens of four years and older produce drones from unfertilised eggs only, because all the spermatozoa have been used up. Several polymorphic forms of drones occur in the same colony, the form depending upon whether they are produced from fertilised or unfertilised eggs. Workers are produced only from fertilised eggs.

THE correct botanical nomenclature of the plants yielding commercial cottons has provided much subject for controversy. A recent paper communicated by Mr. F. Fletcher to the *Cairo Scientific Journal* (November, 1909) discusses the botany and origin of American upland cotton. Evidence is adduced for the opinion that this well-known plant does not show the characters indicated by Miller's type of the species *hirsutum*, but conforms to the description and drawing issued by Tenore for *Gossypium siamense*. The author states that *Gossypium religiosum* of Linnæus also refers to the upland plant, but gives reasons for disregarding this specific name in favour of the former.

THE twentieth number of Notes from the Royal Botanic Garden, Edinburgh, completing the fourth volume, contains several short papers on abnormal developments in plants. Mr. A. J. Gray records an irregular condition in the sporocarp of *Salvinia natans*, where megasporangia were discovered in a microsporangial fruit, and Miss B. Chandler describes cases of anomalous branching at the end of aërial roots of *Tibouchina moricandiana* consequent upon the arrest in growth of the apical meristem. There is also an article, contributed by Mr. F. Darwin, referring to John Hope, a professor of botany in Edinburgh in 1780, and directing attention to certain of his drawings which indicate a knowledge of the light sensibilities of plants much in advance of the published references on the subject.

AN important paper by Dr. M. Greshoff, collating a large number of phytochemical investigations carried out by him in Kew Gardens, is published in the tenth and final index number of the *Kew Bulletin* for 1909, where there also appears the announcement of the author's sudden death. Dr. Greshoff had previously studied the occurrence of alkaloids and hydrocyanic acid in plants, and instituted the investigations here described with the object of discovering new plants of medicinal value, and of testing the presence of chemical constituents as a character of systematic value. The majority of the notes refer to the occurrence of saponin or hydrocyanic acid. Among the plants yielding saponin reactions are several genera of the Leguminosæ, notably Astragalus, which provides some of the American poisonous loco-weeds, and Acacia, of which several species furnish fish poisons; also four genera of the Caprifoliaceæ, three of the Polemoniaceæ and Phytolacca are included. The cyanogenetic list contains, among others, several genera of the Compositæ, Oxytropis, Drosera, Dionæa, Cystopteris, and Davallia.

THE wine industry of South Africa is discussed in a recent number of the *Agricultural Journal of the Cape of Good Hope*. Vines were introduced by the Huguenots, and found congenial soil and climate; the industry has remained in some districts, but is practically stationary, only 6,000,000 gallons of wines and 1,500,000 gallons of brandy being produced. It is urged that these figures are capable of very material improvement. In 1874 Algerian production was no more than that of South Africa, but is now, as the result of careful development, more than 130,000,000 gallons. Cape Colony, it is urged, could produce the light wines of France and Germany and the heavier wines of Spain and Portugal, and there seems to be no insuperable difficulty in the way of creating a flourishing industry.

THE last series of excavations at the amphitheatre known as Maumbury Rings, near Dorchester, has been conducted under the supervision of Mr. St. George Gray, of Taunton Castle, who asks for further support in this undertaking. One remarkable discovery has been made, that of the *cavea* or den in which the animals were housed in readiness for the performances. Here the débris was found to contain coins of the Emperors Constantine the Great and Hadrian, which indicate the approximate date at which games were conducted by the Romans in this amphitheatre.

Dr. R. B. Bean, of the Anatomical Laboratory, Manila, publishes an account of a new cephalograph, an instrument intended to reproduce the outlines of the human head and face, which he has recently invented. It is based on the cranial instruments of Prof. Rudolph Martin, and is an adaptation of the pantograph. He also issues a further instalment of his examination of the Filipino types in the town of Taytay, which corroborates the conclusion at which he had previously arrived, that the population of the archipelago may be resolved into three types —Iberian, Australoid, and Primitive.

A lengthy but interesting study of memorising various materials by a new method forms the subject of a monograph by Prof. E. A. McC. Gamble, separately published by the *Psychological Review*. In this method a series of colours, odours, or syllables (all three materials are used in different experiments), is repeatedly presented to the subject, who manipulates the members of the series after each presentation and attempts to arrange them in their original order. The repetitions of presentation of the series are continued until successful reconstruction of the order is attained. Miss Gamble terms this method the "reconstruction method," and compares the results with those given by previous methods of experiment in memory. She finds that a relatively small number of repetitions is required for successful reconstruction, even at the outset of the experiments and apart from the well-marked improvement-effects of subsequent practice. Compared with the "learning method," in the reconstruction method the increase of difficulty with increasing length of the series is remarkably small. Again, in contrast to the "learning method," in Miss Gamble's method there is no sharp limit to the length of the series which is reproducible in correct order after a single presentation, and the subject remembers fully as many sequences and rather more positions in longer as compared with shorter series.

The Canadian Department of Mines has issued in advance, from its annual report on mineral production, the chapters by Mr. J. McLeish dealing with chromite and asbestos mining in 1907–8. Canada supplies almost the whole of the world's asbestos, and the Canadian output has increased steadily from 27,414 metric tons in 1902 to 60,372 metric tons, of a value of 190,980 dollars, in 1908. The chief mines are in the eastern townships of the Province of Quebec, especially around Thetford. The Canadian output of chromite in 1908 was 7225 short tons (6554 metric tons), a slight increase over that for the previous year, but less than the record in 1906 of 9033 short tons. New Caledonia remains by far the largest producer of chromite; Turkey is second, and Canada has fallen to the fourth place owing to the rapid development of chromite mining in Rhodesia.

Dr. V. Conrad has recently investigated the annual and diurnal variations in frequency of 2497 earthquakes which occurred in the Austrian Alps and neighbouring districts from 1897 to 1907 (*Mitt. der Erdbeben-Kom. der K. Akad. der Wissen. in Wien*, No. 36). The annual variation is well marked, with its maximum in March and minimum in June, the amplitude being 65 per cent. of the mean monthly number of earthquakes. The diurnal variation is also strongly pronounced, the maximum occurring at 2 a.m. and the minimum from 8 a.m. to 4 p.m. Treating the hourly numbers of shocks with the aid of harmonic analysis, the diurnal period is found to have a maximum at 0¾ a.m., and an amplitude which is 87 per cent. of the average hourly number of shocks. In all probability this daily change in frequency is due to the varying conditions under which the earthquakes are observed.

The *U.S. Monthly Weather Review* for May last (which we have recently received) contains part ii. of Prof. C. F. Marvin's article on "Methods and Apparatus for the Study of Evaporation" (see Nature, November 25, 1909). In this part the author describes the various instruments devised for the experiments upon evaporation of water from lakes and reservoirs undertaken by the Weather Bureau. The different kinds of apparatus, which were designed more especially for evaporation from pans, are clearly illustrated and their use fully explained. Among them is a self-registering gauge invented by Prof. Marvin which records, side by side on the same sheet, rainfall, wind, and evaporation, and seems to meet in a satisfactory manner most of the conditions required of such an instrument; the traces are legible, and the apparatus is said to be portable and easily installed.

The January number of the *Illuminating Engineer* of New York contains a well-illustrated article on the electric lighting of the White House, Washington, a dwelling which it characterises as "decidedly unpretentious and plain" in comparison with many mansions of to-day. The imitation candle supporting a miniature incandescent lamp is the unit on which the lighting system is based. In general, they are grouped and supported in an artistic manner, but in one conspicuous case the supports are much too massive.

The United States Coast and Geodetic Survey has recently published an appendix to the report of 1908 which deals with the magnetic observations made on land and by the four vessels engaged in work at sea during the year ending June, 1908. The observations on land are made with a theodolite magnetometer and a dip circle, and those at sea by means of a Lloyd-Creak dip circle checked at intervals by comparison on land with a magnetometer. The whole of the instruments were previously standardised at the Cheltenham Observatory. The present results are summarised in twenty pages of tables. A comparison with previous results shows that the secular increase of westerly deviation on the Atlantic seaboard is about five minutes of arc per annum. Inland the change becomes very small, but rises again to about four minutes per annum increase in the easterly declination at the Pacific seaboard. It may be noted that these secular changes are not quite in agreement with the representation of them as due to a slow drift of the magnetic system of lines to the west.

Under the London Gas Act, 1905, the gas companies were relieved of any obligation to remove sulphur compounds (other than sulphuretted hydrogen), and to replace the standard Argand burner, London Argand No. 1, by another, the London Argand No. 2. The practical effect of this was to enable the gas supplied to be lower in illuminating value by from 1·5 to 2·0 candles. In addition to this, two of the companies were empowered to lower the minimum candle-power from 16 to 14 candles, and in the Gas Light and Coke Company's Act, 1909, the latter company is also permitted to supply 14- instead of 16-candle gas. The 1905 Act also empowered the controlling authority to make tests of the calorific power, and in the 1909 Act, which has just come into force, a statutory minimum net calorific power of 112·5 calories per cubic foot is enforced. As compared with the state of affairs five years ago, the consumer of gas for power or heating purposes has now to burn about 1200 cubic feet of gas in the place of 1000, costing 3*s.* 2½*d.* as against 3*s.*, plus a meter rental (varying with the consumption), plus the extra cost of repairs caused by the additional sulphur present. The consumer, for lighting purposes, if using throughout an incandescent mantle, is not seriously prejudiced; if, however, he retains the batswing burner, his outlay for the same amount of light has increased in the ratio of about 4/3, plus a meter rental and plus an increased cost of internal decoration due to the condensation on the walls and ceilings of an increased amount of sulphuric acid.

THE *Scientific American* for January 15 shows an illustration of the McClean-Lissack automatic rapid-fire gun, which was tested last year by the Ordnance Department of the United States Army. This gun is designed for attacking balloons, and is mounted on a Packard 3-ton automobile truck. The gun fired 3-lb. shots at the rate of 100 per minute, the range being 3½ miles. With brakes on, the truck did not move on firing, and no shock was perceived by those standing on the truck platform. With brakes released there was a slight movement on the recoil, but no shock. Further tests with this gun are being made at Sandy Hook and Springfield for the army, and at Indian Head for the navy. The same article also illustrates two German automobile guns designed for the same purpose. One of these is mounted on an armoured truck of 60 horsepower, capable of a speed of 45 kilometres per hour. The shell from this gun has a maximum height of trajectory of 3800 metres.

THE ninth report to the alloys research committee was presented by Dr. W. Rosenhain and Mr. F. C. A. H. Lantsberry at the meeting of the Institution of Mechanical Engineers on Friday, January 21. Dr. Rosenhain explained that this report dealt with the properties of some alloys of copper, aluminium, and manganese, and is confined to some of the more interesting alloys likely to be of practical service. The greater part of the work was confined to alloys containing less than 11 per cent. of aluminium, and also less than 11 per cent. of manganese. It is impossible to state adequately and briefly the enormous amount of valuable information resulting from this research—the report occupies 174 pages of the institution's transactions. Specific mention might be made of the great tensile strength exhibited by one of the alloys in the form of a cold-drawn bar, having a yield point of 40·88 tons per square inch and an ultimate stress of 52·08 tons per square inch. This alloy had 9·99 per cent. aluminium, 2·01 per cent. manganese, and 88 per cent. copper. Another alloy shows hardness sufficient to enable it to take a cutting edge that will sharpen a lead pencil. In addition to the mechanical tests and microscopic and freezing-point investigations, corrosion in sea water has been examined. Further and more searching tests on the latter are now proceeding at Portsmouth Harbour, and have also been arranged for in the warmer sea water at Malta Dockyard.

THE January number of the Journal of the Royal Statistical Society begins a new series of the journal, to be issued monthly during the session. It is hoped that the greater rapidity of publication thus secured will be of service, as papers read one month will now be in the hands of fellows, and the public generally, by the middle of the following month instead of sometimes not appearing for three months or more, as is necessarily the case with a quarterly journal. Current notes also form a new section of the journal which it is hoped will increase its general interest.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN FEBRUARY:—

Feb. 4. 5h. Venus in perihelion.
6. 12h. Mercury stationary.
7. 12h. 25m. Uranus in conjunction with the Moon (Uranus 3° 19′ N.).
9. 12h. 36m. Venus in conjunction with the Moon (Venus 13° 34′ N.).
12. 0h. Venus in inferior conjunction with the Sun.
13. 13h. 22m. Saturn in conjunction with the Moon (Saturn 1° 18′ N.).
15. 6h. 12m. Mars in conjunction with the Moon (Mars 3° 1′ N.).
19. 17h. Mercury at greatest elongation west of the Sun.
19. 21h. 33m. Neptune in conjunction with the Moon (Neptune 4° 10′ S.).
20. 3h. Venus at greatest heliocentric latitude north.
,, 17h. 34m. Jupiter in conjunction with the Moon (Jupiter 2° 29′ S.).

MARS.—Readers of these columns should be fairly well acquainted with Prof. Lowell's views concerning the Martian features and their significance, but they will find interesting the comprehensive summary given by Prof. Lowell in No. 13 of *Scientia*, the international science review published at Bologna, and obtainable from Messrs. Williams and Norgate. Therein the author reviews the observations of the melting snow-caps, of the "canals" and oases, which, by virtue of their dependent vegetation, undergo striking changes in conformity with the Martian seasons, and the theoretical considerations which have led him to conclude that Mars is habitable by organisms not essentially different from those with which we are acquainted. That Mars has no water except that contained in its atmosphere and that which forms the snow-caps, Prof. Lowell avers, but he contends that that water is artificially "engineered" in such a way that organic existence is rendered possible.

CAROLINE HERSCHEL AND HER COMET SEEKER.—At the present moment, with the subject of comets so much to the fore, an article which appears in the January number of *Himmel und Erde* is of especial interest. The writer gives many details of Caroline Herschel's strenuous life and describes her labours with the comet seeker. A facsimile reproduction of a letter, dated August 5, 1831, from her to Director Hausmann, tells how the comet seeker was made and how she wished it to be used after she had finished with it. The instrument was made of odds and ends by her brother "between breakfast and dinner." "The tube had once been used as a Newtonian finder to the 20-foot reflector. The circular board once served for a fly-wheel in some experiment; and for the pole, I was sent to the scullery to find a mopstic. The rest was sawed and chopped in the shapes as they were wanted—as for plaining we could do without, there was no time for niceties." Yet, she adds, it stood for forty-seven years without wanting a single repair, travelling all over the house and garden, at Slough, many a night; and with it she discovered five of the eight comets credited to her name.

EDDY FORMATION IN THE WAKE OF PROJECTING OBSTACLES.

CONSIDER a stream bounded by and moving parallel to the plane OX, with velocity U, and containing a stationary vortex at A (a, b), or, what is the same thing, an unbounded fluid containing a stationary vortex-pair at A, B (Fig. 1). With the notation $w=\phi+\iota\psi$, $z=x+\iota y$, ϕ=velocity potential, ψ=stream function, the potential function is given, for this case, by

$$w=\mathrm{U}\left(z+2ib\log\frac{z-a-ib}{z-a+ib}\right).$$

Inside a certain surface OQP, the stream lines are closed curves and the motion is cyclic; outside, the fluid streams past the surface as if it were a solid obstacle, as is well known (*e.g.* Lanchester, "Aerodynamics," § 80). If the bounding surface meets the plane boundary OP at O, and O is the origin, then $dw/dz=0$ when $z=0$, whence we easily have $a=b\sqrt{3}$ in the above expression.

Now substitute $z=\sqrt{z'}$, and the solution is obtained of a *continuous* motion round the straight edge past O, with a single vortex in the dead water in the wake of the edge (Fig 2).

Making the substitution, we now write

$$w=A\left(\sqrt{z'}+2ib\log\frac{\sqrt{z'}-(\sqrt{3}+i)b}{\sqrt{z'}-(\sqrt{3}-i)b}\right),$$

where A is a constant, and we find that when $z'=0$, $dw/dz'=-A\sqrt{\tfrac{3}{4}}b$.

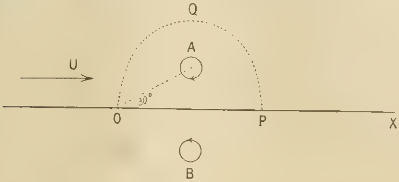


FIG. 1.

The velocity is thus finite where the stream leaves the plate.

With $z'=z^{\frac{3}{2}}$ we get a streaming motion round a rectangular corner with a single vortex in the dead water (Fig. 3), and similarly with $z'=z^n$, where $1<n<2$, we get a streaming motion past a projecting corner with re-entrant angle $n.180°$ (Fig. 4). But here comes the difficulty, *if it is a difficulty*.

Except in the above case of $n=2$, the velocity vanishes at the origin, and, further, the stream line bounding the dead water makes equal angles with the two parts of the fixed boundary; thus, for the right angle of Fig. 3, the boundary of the dead water starts from the origin at an angle of 135° with the two walls, and the dead water projects forward into the stream.

But is it not the fact that when a stream flows through the arches of a bridge, the dead water *does* project into the current, the circulating fluid pushing the stream into the centre and narrowing it? I believe I have seen something of this very kind.

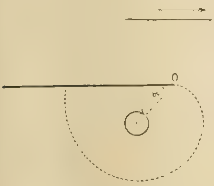

FIG. 2.

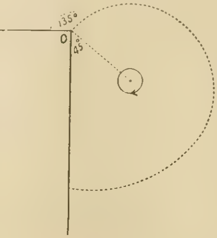

FIG. 3.

As regards the velocity being zero, the same would occur in the hydrodynamical problem representing the motion of two streams meeting at an angle, the velocity vanishing at the projecting angle of the boundary.

If, finally, we apply Schwarz and Christoffel's transformation to our original figure, we can obtain various solutions representing continuous motions past projecting obstacles, maintained by a fixed vortex in the dead water behind them. For example, taking

$$\frac{dz'}{dz}=C\frac{z}{(z-c)^{\frac{1}{2}}(z+c)^{\frac{1}{2}}},$$

or (say),

$$z'=\sqrt{(z^2-c^2)},$$

we get the solution for a broad stream with a pier projecting at right angles to the straight bank, or a current impinging perpendicularly on a lamina, with a couple of vortices situated in the dead water behind it. Moreover, if $c<2a$, the whole of the back of the plate will be in the dead water (Fig. 5), while if $c>2a$ the current will flow round and on to the plate, leaving dead water only near the edges (Fig. 6).

The whole point which I wish to emphasise is that hydrodynamical solutions can be obtained of cases of eddy formation in the wake of a projecting obstacle by taking Fig. 1 and the corresponding formula, and transforming by the usual methods of conformal representation, *transforming the point O of Fig. 1 into the projecting or re-entrant angle.* No other point can be so transformed without making the velocity infinite, except P. We should then have the vortices in front of the obstacle, and this would certainly give a solution of the hydrodynamical equations, but it is difficult to see how vortices would get to the right points, and uncertain whether they would be stable there.

I have seen nothing like these solutions, yet it is hard to imagine that anything so simple can have escaped attention in a well-worn subject like hydrodynamics, especially as the motions bear a strong resemblance to certain observed phenomena. If it should transpire that these problems have been solved before, it seems desirable that attention should be directed to them in view of the importance which such problems have assumed in connection with aërial and other navigation.

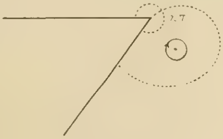

FIG. 4.

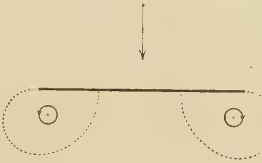

FIG 6.

G. H. BRYAN.

THE NEW COMET (1910a).

IN those places where there has been a clear horizon at sunset during the past week, the new comet has provided a striking spectacle for thousands of observers. The observations made at the established observatories will have to be reduced and discussed, and some time will elapse before they are generally available, so at present we have only the meagre details of telegraphic summaries.

From these we learn that excellent photographs have been obtained at Oxford, Cambridge, Dublin, Stonyhurst, and other observatories, including the Harvard, Yerkes, and Lick institutions. Numerous observers have recorded changes in the appearance of the comet, and it will be interesting to see if these are shown on the photographs.

The elements and ephemeris issued from Kiel are evidently considerably in error; according to Prof. Turner, the error was 3° in declination on January 26, and was increasing 40′ daily. On that day the comet's position was determined at 5.35 p.m. by Dr. Rambaut, at the Radcliffe Observatory, as R.A.=21h. 20m. 40s., dec.=2° 17′ S.; according to the ephemeris, it should have been approximately 21h. 26·9m., 0° 52·5′ N. According to Mr. Crommelin, speaking at the British Astronomical Association, the perihelion distance given in the elements, viz. nearly 4,000,000 miles, is probably much too small. Prof. Kobold has calculated the following elements and ephemeris from observations made on January 18, 20, and 23:—

Elements.

$T = 1910$, January 17·07 G.M.T.
$\omega = 311^\circ\ 53'$
$\Omega = 83^\circ\ 59'$
$i = 138^\circ\ 25'$
Perihelion dist. = 0·109

Ephemeris 5 p.m. *G.M.T.*

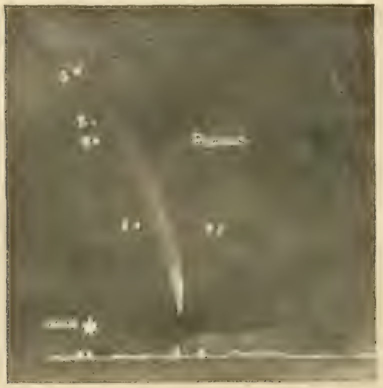
The spectrum of the comet has been observed a number of times at Cambridge, and found to consist of a bright yellow line in a continuous spectrum, thus far confirming the Lick observation. To the *Times* Sir Robert Ball reported this line as being due to sodium or helium, and stated, on January 26, that it was growing fainter. In a subsequent interview Mr. Hinks is reported to have said that Prof. Newall's observations showed that the spectrum of the comet's tail was purely monochromatic, the one line being due to sodium or helium, probably the latter. It will be remembered that Copeland and Lohse observed bright yellow lines in the spectrum of the great comet of 1882, but they were confirmed by Thollon and Gouy in ascribing them to the sodium, D, lines; further, they found them displaced towards the red sufficiently to give a measure of the comet's velocity of recession which agreed fairly well with the velocity determined geometrically. Should the presence of helium in the spectra of comets which have small perihelion distances be established, it might throw more light on Prof. Newall's suggestion that possibly the cyanogen spectrum so frequently observed is produced in the medium through which the comet is travelling; but the observation of cometary spectra is a delicate one, and not until the details of the observations have been thoroughly discussed by those who made them may any semblance of a definite conclusion be arrived at.



View of the New Comet on January 29 (W. E. Rolston).

Prof. Dreyer reports (the *Times*, January 27) that observations made with the 10-inch refractor at Armagh on January 21 and 24 showed a fan-shaped jet on the side of the comet's head turned towards the sun. The matter [illegible] from the fan, and turning back on both sides to form the tail, was distinctly broader south-east of the nucleus than west of it.

Observations at the London observatories have been greatly interfered with by the smoke and haze at the horizon and by clouds. On January 25 the comet was "glimpsed" at Greenwich, and its position was determined the following day.

Successful photographs were obtained on January 28 and 30, and show, in addition to the two main streamers, a much fainter tail which makes a considerable angle with the main tail and gives the comet an appearance similar to that of the great southern comet of 1901.

At the Solar Physics Observatory, South Kensington, Dr. Lockyer saw the comet on Friday evening, January 28, just before 6 p.m., but there was not time to determine its position exactly before clouds again interfered.

Visual observations made at South Harrow on January 29 by Mr. Rolston showed the comet as a magnificent object with a curved tail extending nearly to ξ Pegasi, that is to say, about 20°. The rough sketch reproduced herewith shows the relative position and extension at 6.20 p.m.

Mr. F. C. Constable, of Wick Court, near Bristol, directs attention to a projection extending from the base of the double tail on the side nearer to Venus. In a rough sketch, made at 6.20 p.m. on January 30, he shows this projection as a short, bushy tail inclined some 20° to the axis of the main tail.

Father Cortie states (*Times*, January 29) that on January 26 the comet was seen at Stonyhurst from 5.40 to 7 p.m.; the nucleus was as bright as a first-magnitude star, and the tail could be traced to a distance of 10°. Observed with the 15-inch refractor, the region near the head showed a deep, wide, dark segment running down the tail, recalling to mind the drawings of Donati's comet made by Bond and Pape.

Two photographs taken with the 6-inch Dallmeyer portrait lens show a cloud of particles to the east of the main tail, bounded by a ray making an angle of about 30° with the main axis; presumably this is the projection also observed by Mr. Constable.

On the Stonyhurst photographs the tail can be traced to a distance of 4°, and has the appearance of being a hollow cone, the two bright wings of the tail being the sides of the cone in projection. A glimpse at the spectrum with a small McClean direct-vision spectroscope showed that it was continuous, with a decided brightening in the green, presumably due to a hydrocarbon band; the colour of the comet was decidedly yellowish.

A number of observations are recorded in No. 4385 of the *Astronomische Nachrichten*. M. Gonnessiat, Algiers, suggests that between January 19 and 20 the brightness decreased two magnitudes, and other observers record the rapid decrease. On January 23 Prof. Kobold found the nucleus to be of the third magnitude and the length of the tail to be 15°. From the *Times* (January 31) we learn that, presumably on January 28 or 29, Prof. Nijland, Utrecht, saw a tail 30° long, strongly convex towards the west, and reaching a few degrees to the left from α Pegasi. On Saturday Prof. Turner recorded a faint tail 15° or 20° long. Mdlle. de Robeck, of Inistioge, Kilkenny, reports that the comet was well seen at that place on the four nights succeeding January 22, and provided a fine spectacle just after sunset; she likens it to an egret's plume, which stood out with remarkable clearness against the golden-red background of the sunset sky.

A *Times* correspondent, writing from Malvern, directs attention to a remarkable glare which he saw, on January 30, extending from the concave, or southern, side of the tail well up into the square of Pegasus. This lateral extension through an angle of nearly 80° set with the stars.

THE MESSINA EARTHQUAKE AND THE ACCOMPANYING SEA-WAVES.

A SUMMARY of Dr. M. Baratta's preliminary report on the Messina earthquake has been given recently in NATURE (December 16, 1909, p. 203). Since then two other memoirs have appeared, one a preliminary report by Prof. Omori (Bulletin of the Imperial Earthquake Investigation Committee, vol. iii., No. 2, Tokyo), and the other a detailed account by Prof. G. Platania of the accompanying sea-waves (*Boll. della Soc. Sism. Ital.*, vol. xiii.).

Prof. Omori states that the area of violent motion was elliptical in form, and about 30 km. long from north to south and about 20 km. wide. Judging from the form and position of this area, the origin seems to be situated beneath the Straits of Messina, and the directions of maximum motion at several places radiate from a spot within the Straits between Messina and Reggio, and somewhat nearer the latter town. The sea-waves caused the greatest damage along the Calabrian coast from Pellaro to Lazzaro, where many houses were destroyed by them, and the sandy shore-ground to a maximum breadth of 100 metres was swept away. It is remarkable that the sea-waves were greatest at those places where the shock was not most violent. They appear to have radiated from two centres, which may, however, be portions of a continuous zone of disturbance. Prof. Omori believes that the sea-waves were principally due to the depression of the ground under the portion of sea in question. This latter action, he says, might consist in the vertical settlement through one or two metres of the loose superficial deposits at the bottom of the Straits, such as was known to occur along the shores. The report is illustrated by some interesting maps and diagrams. One of these, here reproduced (Fig. 1), shows the curved band along which lie the areas of violent motion of thirteen great earthquakes in central and southern Italy. These areas being almost distinct, Prof. Omori concludes that great disturbances are not repeated from one and the same centre, that Messina and Reggio are therefore comparatively safe from further harm, while the portions of the seismic band intervening between those mapped are, seismically, the most dangerous in southern Italy.

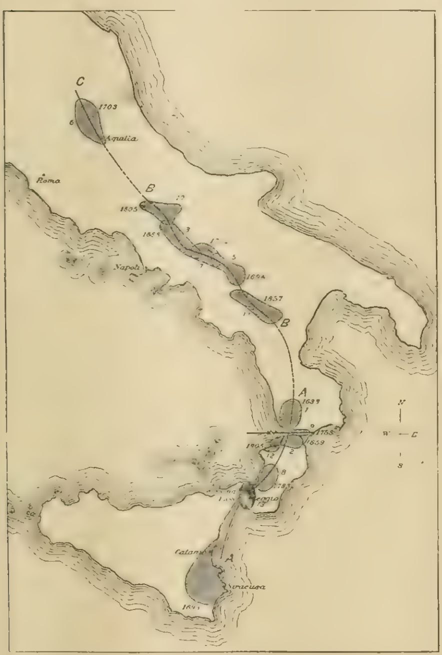


FIG. 1.—Map showing the mutual relations of the great destructive earthquakes in Central and Southern Italy. The shaded area No. 13 is the violent motion district of the Messina-Reggio Earthquake; the other areas, Nos. 1–12, are the similar districts for the previous twelve great earthquakes.

Prof. Platania's report on the seismic sea-waves is one of unusual interest and value. According to Prof. Omori, the maximum height of the waves (of 10·6 metres) was reached on the Calabrian coast between Pellaro and Lazzaro, but for the opposite coast, at S. Alessio, Prof. Platania gives a height of 11·7 metres, or 37 feet. All along the east coast of Sicily the waves were perceptible, though at the northern point (Torre di Faro) they only attained a height of 0·8 metre, and at the southern point (Capo Passero) of 1·5 metres. Along the north coast they were observed as far as Termini, and along the south coast as far as Porto Empedocle. The limits along the Calabrian coast are still unknown. In the Lipari Islands they passed unnoticed, while they were very conspicuous at Malta. At Catania the mareograph was inundated, and the driving clock was stopped by the shock; but good records were given by the mareographs at Malta, Palermo, Mazzara, Cagliari, Ischia, Naples, Civitavecchia, Livorno, and Ravenna. With the exception of Cagliari, the period of the oscillations was approximately the same at each place as that of the seiches due to meteorological causes—a coincidence already noticed by Omori and Honda in other cases. The wave-velocity obtained from the formula $V=\sqrt{(gh)}$ is always much greater than the observed velocity by from 25 to 57 per cent. Taking variations of depth, however, into account, the discrepancies tend to disappear. Of the four submarine cables beneath the Straits from Torre del Faro to Bagnara, only one was broken, and this was close to the shore, and was probably caused by the drifting of a ship's anchor. Two telephone cables were broken by the earthquake, one at about 3 km. from Gallico, and at a depth of 500 metres, the other at about 12 km. east of Vulcano. Interruptions also occurred in the Malta-Zante cable ten and eighteen hours after the shock, and at distances of eighty and fifty-eight miles from Malta.

C. D.

THE MARINE AQUARIUM, MADRAS.

THE Marine Aquarium at Madras, which has recently been thrown open to the public, deserves notice as it is the first institution of its kind in India, if, indeed, it is not the first in the tropics. It owes its inception to Lord Ampthill, who, while Governor of Madras some four years ago, drew up in conjunction with Mr. Edgar Thurston, superintendent of the Madras Museum, the first rough plan of a public aquarium. The building, a low, unpretentious brick edifice, is situated on the seaward side of the famed Madras Marina, less than a hundred yards from the sea. The main entrance leads into a large paved area with a central fresh-water pond and fountain, and on either side five tanks with plate-glass fronts, lit from above, each measuring $7 \times 3 \times 3\frac{1}{2}$ feet. The entire seaward side of the central area is occupied by a large open tank, at present stocked with turtles (*Chelone midas*). On either side of the entrance passage are two rooms designed for committee meetings, for storage of materials, &c., and one of them is at present occupied by the aëration plant.

With the exception of two tanks for fresh-water fish (at present containing species of Megalops, Ophiocephalus, Notopterus, &c.), which are oxygenated by living Vallisneria, the remaining eight contain salt water, which circulates from tank to tank, and in addition are supplied with air from two compression cylinders, forced into each tank through a filter candle. At present the cylinders are filled by hand-pumps, but the use of an oil engine is contemplated. Sea water is conveyed to a covered well in the rear of the aquarium along a pipe filled by hand at the seaward end. From the well it is pumped into filter beds, and from these passes to large elevated cisterns, whence it is distributed to the tanks. The shore water on the Madras coast is so disturbed by the surf that this filtration is unavoidable, though the removal thereby of small organisms is undoubtedly a drawback. The water which has circulated through the aquarium tanks can, if desired, be brought back to the filter beds and used a second time.

The director of the aquarium is the superintendent of the Madras Museum, and he is assisted by a local committee. A small admission fee is charged, and already there are signs of the place becoming very popular, more than 1100 visitors having been admitted on a single day. The magnificent colours of many of the fish, in particular, form a most attractive display. The exhibits include sea-snakes (Enhydrina and species of Distira), and among the fish species of the following:—Ginglymostoma, Stegostoma, Chiloscyllium, Muræna, Arius, Therapon, Serranus, Lutjanus, Myripristis, Trachynotus, Pterois, Caranx, Antennarius, Heniochus, Julis, Teuthis, Balistes, Tetrodon. The invertebrates comprise cuttle-fish, holothurians, hermit-crabs (Clibanarius, &c.), swimming-crabs (Scylla and Neptunus), lobsters (Panulirus), prawns (Penæus), &c. All the specimens have been taken on the Madras coast within a few miles of the aquarium.

INDIAN MUSEUM PUBLICATIONS.

According to the report for 1908–9, the organisation of the Indian Museum has been in need of reform, and the views of the trustees in this respect are shared by the Government of India. The trustees have accordingly "accepted the Government of India's proposals as regards fresh legislation whereby a re-organisation of the museum may be effected. The two main principles that they have had before them in the suggestions they have made to the Government as regards this new legislation have been (1) that each section of the museum should be under proper expert management, and (2) that the heads of the different sections should be *ex officio* trustees themselves. They believe that the new Act which it is proposed to introduce shortly, and of which they have received a draft, will enable them to give effect to these principles.

"The trustees have also to express their gratitude to the Government of India for the support given them in their proposals regarding an increase in the scientific staff and in the pay of the superintendent of the natural history section. They are of the opinion that the alterations sanctioned in these respects will not only enable them to retain the services of their officers in a way that has not proved possible in the past, but will also increase the utility of the museum in many directions. . . . They note with satisfaction the increase, not only in the collections, but also in the scope of the scientific work accomplished by these means; but they are convinced that only a permanent re-organisation of the staff such as has now been rendered possible will enable the museum to maintain and expand its work as a centre of zoological work both purely scientific and directly practical."

No. 3 of the second volume of "Memoirs of the Indian Museum" is devoted to a description, by Dr. R. E. Lloyd, of the deep-sea fish caught by the R.I.M.S. ship *Investigator* during the present century. Colonel Alcock's catalogue of the deep-sea fish taken by the same vessel during last century was published ten years ago, and the present memoir includes notices of such forms as have been named since that date, together with the descriptions of five new genera and species. Four of the new genera appear to be nearly allied to previously known types, but the small, tadpole-like *Liparoides beauchampi* differs from other deep-sea Cyclopteridæ (misprinted Clycopteridæ in the memoir) by the possession of a diphycercal tail and small pelvic fins not fused into a sucker. The memoir concludes with a notice of supposed evidence of mutation in a small pediculate fish of the genus Malthopsis from the Andamans. These fishes were taken from four separate but not very distant stations in the Andamanese Sea, where they appear to form distinct communities; they include five types differing from one another in the relative breadth of the disc and the form and arrangement of the dermal ossicles. These differences can scarcely, however, be regarded as of specific value, while as two or more types occur at each station they obviously do not indicate local races.

The trustees have sanctioned the publication of an annotated list of the Asiatic beetles in the collection of the Indian Museum, under the editorship of the superintendent of the natural history section, of which the first part, dealing with the tiger-beetles (Cicindelinæ), has been issued. The text is in somewhat small type, and it is unfortunate that the specific names are printed in italics similar to those used for the publication-references. Moreover, the references are not free from misprints, as witness *Deutshe* on p. 9, while to others than specialists such references as *Jahrb.* (p. 10) and "*Ent.*" (p. 12) are meaningless.

The third part of vol. iii. of "Records of the Indian Museum" contains a large number of papers dealing mainly with invertebrates, and especially insects. Dr. Annandale has, however, a note on lizards from Travancore, in which reference is made to colour-changes in *Charasia blanfordiana*, a relative of the well-known *Calotes versicolor*. The lizards of this genus appear to take the place in India occupied in the Himalaya, and Asia and Europe generally, by Agama. The colour-changes do not seem always for the purpose of concealment, as the author has seen a specimen temporarily pale in colour basking on a red mud-wall, and a second in full sunshine on a black rock. Other specimens, on the contrary, in similar situations, were more in harmony with their surroundings in the matter of colouring.

MENDELEEFF'S LIFE AND WORK.[1]

To many of the present generation of English chemists the commanding, patriarchal figure of Mendeléeff was quite familiar. Though his several visits to London were often connected with official business of the Russian Government Department of Weights and Measures, of which he was the chief official during the later years of his life, he came several times with more purely scientific objects. In 1889 the occasion of his presence in London was the Faraday lecture, which he had been invited to give to the Chemical Society, but which, owing to a sudden and urgent recall to his home, he was unable to deliver in person. His last appearance in this country was in November, 1905, when the Copley medal was awarded to him by the Royal Society.

The Chemical Society can see his face no more, and all that it can now do is to inscribe high on its roll of honour the name which, more than any other, will be for ever associated with the development of the great generalisation known as the periodic system of the elements.

Dmitri Ivanovitsch Mendeléeff[2] was the fourteenth and youngest child of his parents, Ivan Pavlovitsch and Maria Dmitrievna, *née* Kornileff. His father, a former student of the Chief Pedagogic Institute of St. Petersburg, obtained the appointment of director of the gymnasium at Tobolsk, in Siberia, where he met Maria Dmitrievna, who became his wife. After a few years at Tobolsk he was transferred to school directorships in Russia, first at Tambov and afterwards at Saratov; but in order to satisfy the ardent wish of his wife, he took advantage of an opportunity of exchange, by which he became once more director of the college at Tobolsk, and the family returned to Siberia. Here on January 27, 1834 (O.S.) was born Dmitri Ivanovitsch, the youngest son. Soon after his birth the father became gradually blind from cataract in both eyes, and was obliged to resign, the whole family, including eight children, having to subsist on a small pension of 1000 roubles (about 100*l.* per annum). The mother, Maria Dmitrievna, belonged to the old Russian family Kornileff, settled at Tobolsk. They were the first to establish in Siberia the manufacture of paper and glass. In 1787 the grandfather of Dmitri opened at Tobolsk the first printing press, and from 1789 produced the first newspaper in Siberia, the *Irtysch*. The glass works were situated in the village of Aremziansk, a short distance from Tobolsk.

There can be no doubt the mother was a woman possessed of remarkable vigour of mind, who exercised great influence over her children. Her activity and capacity are further illustrated by the fact that when her husband became blind she revived the business of the glass works, and carried it on until after his death from consumption in 1847.

---

[1] The Mendeléeff Memorial Lecture delivered before the Chemical Society on October 21, 1909, by Sir William A. Tilden, F.R.S. Abridged from the Journal of the Society for December, 1909.

[2] For many of the details of Mendeléeff's career and of his home life the writer is indebted to the family chronicle compiled, soon after his death, by his niece, N. J. Gubkina (*née* Kapustina), and published in St. Petersburg, also to pamphlets by A. Archangelsky and P. J Robinowitsch. He also desires to express his thanks to Mr. D. V. Téquier, of St. Petersburg, as well as to several Russian friends, for valuable assistance in translation.

Tobolsk was at that time a place of banishment for many political exiles, the so-called Decembrists, one of whom, Bassargin, married Olga, an elder sister of Dmitri. To these Decembrists the boy owed his first interest in natural science. His mother had always cherished the hope that at least one of her children would devote himself to science, and accordingly, after her husband's death and the destruction of the glass works by fire, and spite of failing health and scanty means, she undertook the long and tedious journey from Tobolsk to Moscow, accompanied by her remaining children, Elizabeth and Dmitri Ivanovitsch, with the object of entering the latter, then nearly fifteen years of age, at the university. Disappointed in this object, owing to official difficulties, she removed in the spring of 1850 to St. Petersburg, where ultimately, with the assistance of the director, Pletnoff, of the Central Pedagogic Institute, a friend of her late husband, she succeeded in securing for her son admission to the physico-mathematical faculty of the institute, together with much-needed pecuniary assistance from the Government.

The debt which Dmitri Ivanovitsch owed to his mother he acknowledged later in the introduction to his work on "Solutions," which he dedicated to her memory.

In the Pedagogic Institute Dmitri Ivanovitsch was thus able to devote himself to the mathematical and physical sciences under the guidance of Profs. Leng and Kupfer in physics, Woskresensky in chemistry, and Ostragradsky in mathematics. Unfortunately, at the end of his course his health failed, and about this time his mother died. Having been ordered to the south, he fortunately obtained an appointment as chief science master at Simferopol, in the Crimea. The southern climate soon alleviated the serious symptoms of lung disorder, and removal being necessary in consequence of the Crimean War, he was able soon afterwards to undertake a post as teacher of mathematics and physics at the gymnasium at Odessa. In 1856 he returned to St. Petersburg, and at the early age of twenty-two was appointed privat-docent in the University, having secured his certificate as master in chemistry.

At this time he appears to have passed rapidly from one subject to another, but he soon found matter for serious and protracted study in the physical properties of liquids, especially in their expansion by heat; and when, in 1859, by permission of the Minister of Public Instruction, Mendeléeff proceeded to study under Regnault in Paris and afterwards in Heidelberg, he devoted himself to this work, communicating his results to Liebig's *Annalen* and the French Academy of Sciences. Returning two years later to St. Petersburg, he secured his doctorate, and was soon afterwards appointed professor of chemistry in the Technological Institute. In 1866 he became professor of general chemistry in the University, Butlerow at the same time occupying the chair of organic chemistry.

As a teacher, Mendeléeff seems to have possessed a special talent for rousing a desire for knowledge, and his lecture-room was often filled with students from all faculties of the University. Many of his former students remember gratefully the influence he exercised over them.

One of Mendeléeff's most remarkable personal features was his flowing abundance of hair. The story goes that, before he was presented to the late Emperor, Alexander III., his Majesty was curious to know whether the professor would have his hair cut. This, however, was not done, and he appeared at Court without passing under the hands of the barber. His habit was to cut his hair once a year, in spring, before the warm weather set in. His eyes, though rather deep-set, were bright blue, and to the end of his life retained their penetrating glance. Tall in stature, though with slightly stooping shoulders, his hands noticeable for their fine form and expressive gestures, the whole figure proclaimed the grand Russian of the province of Tver.

At home, Mendeléeff always wore an easy garment of his own design, something like a Norfolk jacket without a belt, of dark grey cloth. He rarely wore uniform or evening coat, and attached no importance to ribbons and decorations, of which he had many.

As to his views on social and political questions, many people thought him a rigid monarchist, but he said of himself that he was an evolutionist of peaceable type, desiring a new religion, of which the characteristic should be subordination of the individual to the general good. He always viewed with much sympathy what is called the feminine question. At the Office of Weights and Measures he employed several ladies, and about 1870 he gave lectures on chemistry to classes of ladies.

Mendeléeff held decided views on the subject of education, which he set forth in several publications, especially "Remarks on Public Instruction in Russia" (1901). Here he says:—"The fundamental direction of Russian education should be living and real, not based on dead languages, grammatical rules, and dialectical discussions, which, without experimental control, bring self-deceit, illusion, presumption, and selfishness." Believing in the soothing effect of a vital realism in schools, he considered that universal peace and the brotherhood of nations could only be brought about by the operation of this principle. Speaking of the reforms desirable, he says that "for such reforms are required many strong realists; classicists are only fit to be landowners, capitalists, civil servants, men of letters critics, describing and discussing, but helping only indirectly the cause of popular needs. We could live at the present day without a Plato, but a double number of Newtons is required to discover the secrets of nature, and to bring life into harmony with the laws of nature." Mendeléeff was evidently a philosopher of the same type as our own Francis Bacon.

In 1863, when twenty-nine years of age, Mendeléeff married his first wife, *née* Lestshoff, by whom he had one son, Vladimir,[1] and a daughter, Olga; but the marriage proved unhappy, and after living apart for some time there was a divorce. In 1881 he married a young lady artist, Anna Ivanovna Popova, of Cossack origin, and lived first at the University and afterwards in the apartments built for the director at the Bureau of Weights and Measures. Here his younger children were born, Lioubov (Aimée), Ivan (Jean), and the twins, Maria and Vassili (Basile).

In 1890, in consequence of a difference with the administration, Mendeléeff retired from the professorship in the University. During the disturbances among the students in that year, he succeeded in pacifying them by promising to present their petition to the Minister of Education. Instead of thanks for this service, however, the professor received a sharp reprimand from the authorities for not minding his own business. The consequence was that Mendeléeff resigned. Independently of the petition, however, there were probably deeper reasons for his being out of favour with the Ministry, connected with his irreconcilable enmity to the classical system of education already referred to. Of this he had made no secret, and it had already brought him into conflict with the authorities. In 1893, however, he was appointed by M. Witte to the office of director of the Bureau of Weights and Measures, which he retained until his death.

Such are the chief features of a great personality. If it be admitted that stories are told of his occasional irritability of temper, we can well place on the other side of the account the cordial relations always subsisting between the professor and his assistants, the confidence and respect between the master and his servants, the deep affection between the father and his children, which are known to have persisted throughout his life, and which could be illustrated by many anecdotes. These stories merely serve "to give the world assurance of a man."

For us who live on the other side of Europe, separated as we are by race, by language, by national and social customs, and by form of government, it is not easy to understand completely the texture of such a mind, the quality of such genius, and the conditions, social or political, which may have served to encourage or to repress its activity. The Russian language may be eloquent, expressive, versatile, and harmonious, or it may possess any other good quality that may be claimed for it by those to whom it is a mother tongue, but the fact remains that it is a barrier to free intercourse between the Russian people and the world outside the Russian Empire. This alone creates a condition which must influence the development of thought, and must give to Russian science and philosophy a colour of its own. Mendeléeff was, like many educated Russians, a man of very liberal views on such subjects as education, the position of women, on art and science, and probably on national government. We can hardly guess what would be the influence on such a nature of a rigid administrative *régime* which forbids even the discussion of such questions. We in England are almost unable to imagine such a state of things as would be represented by the closing of, say, University College for a year or more, because the question whether the House of Lords ought to be abolished had been debated in the Students' Union. Imagine the professor of chemistry, along with his colleagues, for such a reason deprived of the use of his laboratory by the police, and only allowed to resume his studies when someone down at Scotland Yard thought proper. Such being the experience of most of the Russian universities and technical high schools, it is not surprising that the output of Russian science, notwithstanding the acknowledged genius of the Russian people, appears sometimes comparatively small. The amount of work done by Mendeléeff, both experimental and theoretical, was prodigious, and all the more remarkable considering the cloudy atmosphere under which so much of it was accomplished.[1]

---

[1] Died in 1899, aged thirty-four.

In 1882 the Royal Society conferred on Mendeléeff, jointly with Lothar Meyer, the Davy medal. In 1883 the Chemical Society elected him an honorary member, and in 1889 it conferred upon him the highest distinction in its power to award, namely, the Faraday lectureship, with which is associated the Faraday medal. In 1890 he was elected a Foreign Member of the Royal Society, and in 1905 he received the Copley medal. So far as England is concerned, his services to science received full acknowledgment. It is all the more remarkable, therefore, that he never became a member of the Imperial Academy of Sciences of St. Petersburg.

Towards the end of 1906 Mendeléeff's health began to fail. Nevertheless he was able to attend the Minister on the occasion of an official visit in January to the office of Weights and Measures, but he caught cold and, enfeebled as he had been by influenza in the preceding autumn, inflammation of the lungs set in. Retaining consciousness almost to the last, he requested even on the day of his death to be read to from the "Journey to the North Pole," by his favourite author, Jules Verne. He died in the early morning of January 20 (O.S.), 1907, within a few days of his seventy-third birthday. He was buried in the Wolkowo Cemetery beside the graves of his mother and son.

Turning now to a survey of Mendeléeff's work as a man of science, it will be sufficient if we pass lightly over his first essays. Like so many other chemists, he began by handling simple questions of fact, his first paper, dated 1854, when he was twenty years of age, being on the composition of certain specimens of orthite. It was not until 1859 that he settled down to serious examination of the physical properties of liquids, which led him to a long series of experiments on the thermal dilatation of liquids, of which the chief ultimate outcome was the establishment of a simple expression for the expansion of liquids between 0° and the boiling point. This formula is liable to the same kind of modification which has been found necessary in the case of gases. It is, of course, applicable only to an ideal liquid from which all known liquids differ by reason of differences of chemical constitution and consequent differences of density, viscosity, and other properties.

Mendeléeff devoted a large amount of time and of experimental skill to the estimation of the densities of various solutions, especially mixtures of alcohol and water and of sulphuric acid and water, and of aqueous solutions of a large number of salts. In 1889 he embodied the whole in the monograph already referred to. In a paper communicated to the Transactions in 1887 (li., 779), he stated his views in the following words:—"Solutions may be regarded as strictly definite atomic chemical combinations at temperatures higher than their dissociation temperatures. Definite chemical substances may be either formed or decomposed at temperatures which are higher than those at which dissociation commences; the same phenomenon occurs in solutions; at ordinary temperatures they can be either formed or decomposed." These views, however, did not prevent his recognising van 't Hoff's gas theory as applicable to dilute solutions.

In conjunction with some of his students, Mendeléeff also studied minutely the question of the elasticity of gases, and published several papers on the subject (see Royal Society Catalogue), extending over a period of some ten years from 1872.

Another subject to which Mendeléeff gave a good deal of attention was the nature and origin of petroleum. Having already reported in 1866 on the naphtha springs in the Caucasus, in the summer of 1876 he crossed the Atlantic and surveyed the oil fields of Pennsylvania. In the course of these investigations, he was led to form a new theory of the mode of production of these natural deposits. The assumption that the oil is a product of the decomposition of organic remains he rejects on a variety of grounds, which are set forth in a communication to the Russian Chemical Society (Abstract, see *Ber.*, 1877, x., 229). Mendeléeff assumes, as others have done, that the interior of the earth consists largely of carbides of metals, especially iron, and that hydrocarbons result from the penetration of water into contact with these compounds, metallic oxide being formed simultaneously. The hydrocarbons are supposed to be driven in vapour from the lower strata, where temperature is high, to more superficial strata, where they condense and are retained under pressure. In 1886, in consequence of rumours as to the possible exhaustion of the Russian oil fields, he was sent by the Government to Baku to collect information, and in 1889 he made a communication on this subject to Dr. Ludwig Mond, which is printed in the Journal of the Society of Chemical Industry (1889, viii., 753).

The influence of the great generalisation known as the periodic law can best be estimated by reviewing the state of knowledge and opinion before the announcement and acceptance of the principle by the chemical world, and subsequently glancing at the influence which, directly or indirectly, it has produced on scientific thought, not only in regard to the great problems to which it immediately relates, but to the whole range of chemical theory.

The use of the expression "atomic weight" implies the adoption of some form of atomic theory; but forty or more years ago Dalton's atomic theory was by many of the most philosophical chemists and physicists regarded as only a convenient hypothesis, which might be temporarily useful, but could not be accepted as representing physical reality. Since that time, however, a variety of circumstances have contributed to consolidate the Daltonian doctrine. The estimation of the ratios called atomic weights has been the subject of research, attended by more and more elaborate precautions to secure accuracy, from the time of Dalton himself onward through successive generations down to the present day. Though the atomic weights of the majority of the common elements are now known to a high degree of accuracy, the acknowledged errors have been sufficiently great to render abortive various attempts to reduce them to any common scheme of mathematical relationship. As is well known, the most important step toward the systematisation of atomic weights was taken about 1860, mainly on the grounds eloquently and convincingly set forth by Cannizzaro,[1] in consequence of which the arbitrary selection of numbers for atomic weights was superseded by the practical recognition of the law of Avogadro and the application of the law of Dulong and Petit, so that a common standard was established. No general scheme of atomic weights was previously possible, partial and imperfect efforts in this direction being represented by Dœbereiner's triads and the principle of homology made use of by Dumas. Only so soon as numbers representing the atomic weights of calcium, barium, lead, and other metals were corrected and brought into the same category as those of oxygen, sulphur, and carbon was there some chance of determining whether these numbers possessed a common factor or were capable of exhibiting mathematical inter-relations which might be regarded as symbolic of physical relations or even directly dependent upon them. The first step in this direction was taken by J. A. R. Newlands, who, after some preliminary attempts in 1864–5, discovered that when the elements are placed in the order of the numerical value of their atomic weights, corrected as advised by Cannizzaro, the eighth element starting from any point on the list exhibits a revival of the characteristics of the first. This undoubtedly represents the first recognition of the principle of periodicity in the series of atomic weights, but whether discouraged by the cool reception of his "law of octaves" by the chemical world or from imperfect apprehension of the importance of this discovery, Newlands failed to follow up the inquiry. It was not long, however, before the matter was taken up by others, and doubtless the improvements in the estimation of atomic weights, following on the work of Stas, then only recently published, inspired greater confidence in the approximate accuracy of the numbers adopted as atomic weights, and thus encouraged inquiry into their relations. The subject is, indeed, an attractive one, for it involves considerations which lie at the foundations of all our notions respecting the physical constitution of matter, and accordingly we find papers by many chemists dealing with the question of these numerical relations. Odling especially seems to have given much thought to the subject, and, ignoring Newlands's previous attempts, he drew up towards the end of 1864[1] a table containing a list of all the then well-known elements, arranged horizontally in the order of their generally accepted groups, and perpendicularly in the order of their several atomic weights. He concludes an article in Watts's Dictionary a few months later with these words:—"Doubtless some of the arithmetical relations exemplified in the foregoing table are merely accidental, but, taken altogether, they are too numerous and decided not to depend on some *hitherto unrecognised* law." It is important to note the words I have italicised.

---

[1] Prof. Walden, at the end of a biographical notice recently published in the *Berichte d. Deut. Chem. Ges.*, April, 1909, gives a list of 262 printed publications by Mendeléeff. These include, not only memoirs on physical and chemical subjects, but books, pamphlets, reports, and newspaper articles relating to exhibitions, to the industries of Russia, to weights and measures, to education, to art, and even to spiritualism.

[1] 1858, and later, Faraday Lecture, 1872.

Such, then, was the state of knowledge about this time. Evidently the way was being prepared, but the prophet had not made his appearance—the seer who could look with the eyes of confidence beyond the clouds of uncertainty which obscured all ordinary vision.

In March, 1869, Mendeléeff communicated to the Russian Chemical Society an enunciation of the principle of periodicity and a statement of some of the consequences of this recognition of the relation of properties to atomic weight throughout the whole range of the known elements, and this statement was accompanied by a table which, while it bears a close resemblance to Odling's table of 1864, was apparently connected in his mind with an idea which became clearer and more decisive in the modifications which he immediately afterwards introduced into the arrangement.

Mendeléeff's First Table of the Elements.

			Ti = 50	Zr = 90	? = 180
			V = 51	Nb = 94	Ta = 182
			Cr = 52	Mo = 96	W = 186
			Mn = 55	Rh = 104·4	Pt = 197·4
			Fe = 56	Ru = 104·4	Ir = 198
			Ni = Co = 59	Pd = 106·6	Os = 199
H = 1			Cu = 63·4	Ag = 108	Hg = 200
	Be = 9·4	Mg = 24	Zn = 65·2	Cd = 112	
	B = 11	Al = 27·4	= 68	U = 116	Au = 197?
	C = 12	Si = [illegible]	= 70	Sn = 118	
	N = 14	P = 31	As = 75	Sb = 122	Bi = 210?
	O = 16	S = 32	Se = 79·4	Te = 128?	
	F = 19	Cl = 35·5	Br = 80	I = 127	
Li = 7	Na = 23	K = 39	Rb = 85·4	Cs = 133	Tl = 204
		Ca = 40	Sr = 87·6	Ba = 137	Pb = 207
		= 45	Ce = 92		
		?Er = 56	La = 94		
		Yt = 60	Di = 95		
		In = 75·6	Th = 118		

From this arrangement, in which the elements are placed in vertical columns, according to increasing atomic weight, so that the horizontal lines contain analogous elements, again according to increasing atomic weight, Mendeléeff deduced the fundamental principle which he expressed as follows:—The elements arranged according to the magnitude of atomic weight show a periodic[2] change of properties.

Previous students of the subject had been, for the most part, struck with the relations obviously subsisting between the members of the several natural families of elements, but had, with few exceptions, failed to perceive that there must be a *general* law binding the whole together. However, Mendeléeff, with that noble sentiment of justice which always animates the truly scientific mind, admits that the idea of a general law had already been foreshadowed by others (Faraday lecture, 1889).

Mendeléeff's table of 1869 was subsequently in 1871 modified so as to assume the form with which we have all been so long familiar, and which is to be found in every modern text-book. Thus it may be claimed for Mendeléeff that he was actually the first, not only to formulate a general law connecting atomic weights with properties, but was the first to indicate its character, and, as himself ("Principles," 1905, ii., p. 28) has pointed out, he was the first "to foretell the *properties of undiscovered* elements, or to alter the accepted atomic weights" in confidence of its validity. The time was, in fact, ripe for the enunciation of this general principle, and, the suggestion once given, the relations embodied in the law could not fail to attract other chemists. Accordingly, in December, 1869, Lothar Meyer, with such knowledge of Mendeléeff's scheme as could be derived from the imperfect German version of his paper of the previous March, proved himself a convinced exponent of the idea by contributing to Liebig's *Annalen* a paper containing a table, substantially identical with that of Mendeléeff, and his famous diagram of atomic volumes, which, more clearly even than the tabular scheme, illustrates the principle of periodicity.

The history of science shows many instances of the same kind. Great generalisations have often resulted from the gradual accumulation of facts which, after remaining for a time isolated or confused, have been found to admit of coordination into a comprehensive scheme, and, this once clearly formulated, many workers are found ready to assist in its development. The case is nearly parallel to the recognition of the operation of natural selection by Darwin and Wallace, or it might be compared to the discovery of oxygen by Priestley and Scheele and the utilisation of this knowledge by Lavoisier. In each case much preparatory work had been done, and a body of knowledge had been gradually accumulated which, when duly marshalled and surveyed by the eye of a master, could scarcely fail to reveal to him the underlying principle. The full consequences, however, would appear only to a few.

I regard it as unnecessary, in the presence of the fellows of the Chemical Society, to review with any detail the multitudinous applications of the scheme of the elements constructed on the basis of the periodic law. These are the commonplaces of modern theoretical chemistry. They are embodied in every text-book of any importance, and are related by every lecturer and teacher as familiar and indisputably recognised consequences of the system. We may therefore pass lightly over the story of the prediction by Mendeléeff of the properties of undiscovered elements, confirmed so remarkably by the discovery of scandium, gallium, and germanium, and related in dramatic language by Mendeléeff himself (Faraday lecture). We may also pass over the applications of the system to the correction of atomic weights, illustrated by the case of beryllium, the recognition of previously unnoticed relations, and the discovery of new elements, notably the companions of argon (Ramsay, Presidential Address to Section B, British Association, 1897, and Proc. Roy. Soc., 1898, lxiii., 437).

It will be more profitable to consider a few of the difficulties which still encumber the application of the law, and which, while limiting our acceptance of it in an unqualified form as applicable to the whole of the elements, tempt the speculative mind to wander in wide fields of conjecture.

Can it be truly said that the elements arranged in the order of their atomic weights show without exception periodic changes of properties? This question has been propounded already, but has never been fully discussed, even by Mendeléeff. An examination of the facts seems, however, to indicate the possibility of some other principle, which, while it does not supersede the periodic scheme, would, if it could be recognised, supplement it.

---

[1] Quart. J. Sci., 1864, i, 643; and Watts's Dictionary, vol. iii., 975.

[2] Here an error in the German translation does an injustice to the original, inasmuch as the Russian word for periodic is rendered "stufenweise" (gradual).

From a consideration of the almost unbroken sequence in the atomic weights of the known elements, it seems probable that few additional elements are to be expected, except possibly one following Mo and another following W, save in the region from Bi to Ra. This suggests the remark that, after all, it is not necessary to assume that the materials of which the earth consists should necessarily include a sample of every possible element indicated by such a scheme. Some which are missing from terrestrial matters may perhaps be responsible for phenomena recognisable by the spectroscope in stars or nebulæ far distant in cosmical space. The unexpected, however, often happens, and, remembering the discovery of terrestrial helium, it is permissible to hope that some of the vacant spaces may hereafter be filled by earthly occupants.

There is one important point to be noted here, namely, that if the so-called rare earth metals, praseodymium, neodymium, samarium, gadolinium, terbium, dysprosium, erbium, ytterbium, and others of which the existence is doubtful, do lie in the position indicated, the original statement of the periodic law breaks down at this point.

One result of the recognition of the periodic law is that theories concerning the genesis of the elements have received a stimulus previously unknown. It is, however, interesting to note the attitude of Mendeléeff toward this question, and the small extent to which this attitude appears to have become modified with the lapse of time. When, in 1889, twenty years after the discovery of the law, he composed the Faraday lecture, he seems to have regarded speculation in this direction as a kind of abuse of the periodic system.

Fifteen years later, after the discovery of the argon group of elements, of the phenomena of radio-activity, and of radium, it became necessary to consider the relations of these substances to the periodic scheme. In a remarkable article contributed to the new Russian Encyclopædia, and subsequently printed as Appendix iii. to the "Principles" (English edition, 1905), Mendeléeff gives a new table of the elements, in which places are found, not only for the argon group and radium, but for two hypothetical elements, which are placed before helium and designated x and y.

The y in the table is supposed to be an analogue of helium, and may be identified hereafter with "coronium," which has been recognised in the sun's coronal atmosphere. This gas would have, according to Mendeléeff, a density about 0·2, and therefore a molecular weight about 0·4, or about one-tenth that of helium.

x is the "ether" of the physicist, for which Mendeléeff, disregarding conventional views, supposes a molecular structure. He also assumes that, like the argon group, this element is chemically inert and possesses a very low density and atomic weight, estimated at 0·000,000,000,053.

Chemists and physicists have, however, found it impossible to resist the fascination of this problem, and accordingly there have been many hypotheses as to the origin of the elements and the nature of their connection with one another. These seem to be inseparable from the periodic scheme itself, which at once provokes the inquiry, Why do these numerical relations occur, and what is the meaning of them if they do not point to a common genesis or the operation of some process of evolution?

Hypotheses concerning the evolution of the elements have hitherto been usually based on the assumption that the successive stages of condensation of elemental matter proceeded from a single primary stuff, which by a process analogous to polymerisation among carbon compounds gave rise to atoms of greater and greater mass, which were stable at the prevailing and any lower temperature. The physical cause of the successive condensations is supposed to be a falling temperature. It is, of course, possible to imagine that if to the stuff of which hydrogen atoms consist are added successive portions of matter of the same kind, stable structures may at intervals result which we know as the atoms of the elements helium, lithium, beryllium, boron, carbon, nitrogen, oxygen, and fluorine, provided the idea of internal structure in these atoms is allowed. Otherwise, from the mere accretion of matter upon a central nucleus, there seems no sufficient reason why there should not have been formed an indefinite number of intermediate masses corresponding to an indefinite number of what would be called elements. Further, it is difficult to understand why simple increase of mass should change, say, oxygen into fluorine, while a further addition of the same kind should change negative fluorine into inert neon or positive sodium. The possibility of the condensation of a single "protyl" so as to produce, at successive though unequal stages of cooling, the elements known to the chemist, has been most ably discussed long ago by Sir William Crookes.

This hypothesis, however, was put forward long before the work of Sir J. J. Thomson and his school was given to the world and the electron was accepted as a physical reality. The hypothesis that one elemental stuff may give rise to the whole array of known elements by a process of condensation accompanied by a loss or gain of electrons, the mass of which is approximately one-thousandth of the mass of an atom of hydrogen, forms the subject of a paper by Mr. A. C. G. Egerton in a recent number of our Transactions (1909, xcv., 239). The atomic weights calculated by his formula agree closely with the experimental atomic weights of the first fifteen elements, but the hypothesis gives no explanation of the facts observed in the physical properties of the elements arranged according to the Mendeléeff scheme, their alternation of odd and even valency, the transition from positive on one side of the table to negative on the other, the periodicity of properties shown by the sudden change of character in passing from fluorine to the next element, whether it be neon or sodium.

Another paper by Messrs. A. C. and A. E. Jessup (*Phil. Mag.*, 1908 [vi.], xv., 21) has recently provided a hypothesis of an entirely different character. From a study of the spectra of the nebulæ, these authors have been led to assume the existence of two hitherto unrecognised elements, to which the names protoglucinum and protoboron are assigned. These with hydrogen and helium are supposed to represent *four* initial substances, or protons, which, by condensation directly or indirectly, give rise to all the rest of the elements. The arguments of these authors are ingenious, but rather artificial in view of the fact that the number of groups in the periodic scheme to be provided for is greater than four.

In the Mendeléeff chart of the elements there is nothing more striking than the gathering of the negative elements toward what may be called the N.E., and the segregation of the positive elements toward the S.W., the centre of the intermediate territory being occupied by elements which play a more or less undecided part. I have elsewhere (Presidential Address, 1905, Trans., lxxxvii., 564) directed attention to the fact that carbon, at any rate, is not directly deposited by electrolysis from any of its compounds, with positive hydrogen on the one hand, or negative chlorine on the other. I believe the same is true of silicon, these two elements standing in a middle position between the extremes occupied by lithium and fluorine respectively.

If we assume that atoms are made up of two parts (protyls), positive and negative, in proportions which determine by the preponderance of one or the other whether the element shall exhibit the positive character of a metal like lithium or the negative character of a halogen, we arrive at a hypothesis which recalls the ideas put forward nearly a century ago by Berzelius. His views are familiar to every student of the history of chemistry, but have long been relegated to the lumber-room of worn-out doctrine. The last few years have, however, given us the remarkable experimental investigations of J. J. Thomson already referred to, and the new conceptions concerning the nature of atoms, which revive the fundamental idea that they are made up of two components.[1]

---

[1] Carnelley, in 1885 (Brit. Assoc. Reports), brought forward the idea "that the elements are not elements in the strict sense of the term, but are, in fact, compound radicals made up of at least two simple elements, A and B." The element A was supposed to be identical with carbon, while to B was assigned a negative weight, −2, and it was suggested that it might be the ether of space. C. S. Palmer (Proc. Colorado Scient. Soc.) assumed the existence of two sub-elements, to which he gave the names "kalidium" and "oxidium," and his views appear to have a general resemblance to the hypothesis suggested in the text. The original article is abstracted in Venables's "Periodic Law," and is referred to in footnotes in Palmer's translation of Nernst's "Theoretical Chemistry."

Setting out the known elements in the order of the numerical value of their atomic weights, we find that between the first three elements, H=1, He=4, and Li=7, the difference, 3, is greater than would be expected by comparison with the differences noticed between the elements of greater atomic weight which immediately follow them. In order to satisfy the hypothesis just put forward, there appears to be wanting an element which should stand in the same relation to fluorine as hydrogen to lithium. This would have an atomic weight 2·7 approximately. Whether this exists, and whether its existence is indicated by the unappropriated spectral lines of nebulæ or corona, can only be a matter of conjecture. Mendeléeff, in his (1905) latest speculations concerning the possibility of still undiscovered elements, has suggested the existence of a new element of the halogen group with an atomic weight about 3;[1] but, as already sufficiently shown, he accepted no hypothesis which involved any idea of the composite nature of the elements. It would therefore have been foreign to his system to employ this element in any such manner.

The conceptions presented to us in J. J. Thomson's work permit of several supplementary hypotheses, especially the idea that if atoms are really made up of smaller corpuscles these are not thrown together in confusion, but, as he has shown, must be distributed within the mass in a definite order, which is determined by the attraction of the electro-positive shell and the self-repulsion of the negative corpuscles included in it. Once the idea of structure within the atom is admitted, the possibility presents itself of there being for the same mass more than one arrangement corresponding to what is called isomerism in compounds.

I have dwelt at some length on these various hypotheses, because the discussion of the subject to which they relate indicates, in my opinion, one of the consequences of the promulgation and general acceptance of the periodic scheme of the elements. This is, however, not the only result of the recognition of its validity and usefulness by chemists generally. That the elements stand in a definite relation to one another implies that their compounds also fall into their places in an orderly system, and consequently a basis is provided for the complete systematisation of the whole science of chemistry. There is scarcely a treatise on chemistry which does not bear evident witness to this influence; and this is perhaps not the least among the services rendered by this generalisation, for not only is the learner enabled to remember a much larger number of facts than previously, but he is led to perceive a connection between phenomena and processes which was almost entirely wanting so long as practical chemistry consisted mainly of a bundle of recipes. Here it is fitting that we should glance at the famous treatise by Mendeléeff himself, "The Principles of Chemistry," of which we possess three editions in English, the last of which, issued in 1905, is a rendering of the seventh edition (1903) of the original. An eighth Russian edition began to be issued in 1905, but is incomplete. To this remarkable book it is impossible to do justice in a brief notice or to communicate to those who have not read it an adequate impression. Clearly it is a work of genius, but such works are not always the most suitable for beginners, though for the advanced student nothing can be more inspiring. The "Principles" embody in reality two distinct treatises, for the text, which is written in an easy style, open to quite straightforward reading, is accompanied by notes which are often more voluminous and usurp entire pages. Even the preface is attended by these commentaries, which are all interesting as showing the spirit of the writer and the restless activity of his mind.

Little more remains to be said. In the seventeenth century Robert Boyle taught us how to distinguish elements from compounds, and how to give to the word "element" a definite connotation clearly distinguishing it from the elusive and fantastic language of the alchemists. In the eighteenth century Lavoisier showed the true nature of the most familiar of chemical compounds, namely, acids, bases, and salts, and helped to lay the foundation of quantitative chemistry. At the beginning of the nineteenth century Dalton gave to chemistry the atomic theory, of which it is not too much to say that it provided the scaffold by the aid of which the entire fabric of modern theoretical chemistry has been built up. Sixty years later this conception, developed and adorned by the labours of an army of earnest workers, has been shown to us in a brilliant new light thrown over the whole theory by Mendeléeff.

The views of Boyle, of Lavoisier, and of Dalton have been corrected by experience and broadened by extended knowledge, but the fundamental and essential parts of their ideas remain, and their names are immortal. In like manner the expression of the periodic law of the elements as known to the present generation is destined, we may believe, to be absorbed into a more comprehensive scheme by which obscurities and anomalies will be cleared away, the true relations of all the elements to one another revealed, and doubts as to the doctrine of evolution resolved in one sense or the other; but as with the atomic theory itself, there is no reason to doubt that the essential features of the periodic scheme will be clearly distinguished through all time, and in association with it the name of Mendeléeff will be for ever preserved among the fathers or founders of chemistry.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. C. Forster Cooper has been appointed demonstrator of animal morphology by the professor of zoology and comparative anatomy for five years from Christmas, 1909.

Dr. Hobson has been appointed chairman of the examiners for the mathematical tripos, part ii. (new regulations), 1910.

The special board for physics and chemistry has appointed Mr. F. W. Dootson as assessor in chemistry to the examiners for the mechanical sciences tripos in 1910.

The Quick professor of biology commenced on February 2 six lectures on the pathogenic Protozoa, to be given on Wednesdays and Fridays. Attendance is free to members of the University. There will be two lectures on February 23 and 25 on "Recent Progress in the Treatment of Protozoal Diseases." These two lectures will be free to all desiring to attend.

The chairman of the board of anthropological studies gives notice that Mr. Roscoe's lectures on the natives of Uganda will be given on Tuesdays, at 5 p.m., in the archæological museum.

Durham.—The University this term comes under the operation of a new constitution established by an unopposed Act of Parliament last session. Originally the effective control of this University rested with the Dean and Chapter of Durham, who founded it, but gradually, after the incorporation of the Newcastle College of Medicine in 1852 and the establishment of the Durham College of Science, now Armstrong College, in Newcastle, actual power passed into the hands of an academic body, the Senate. This body, showing the anomalies of its growth, lately left much to be desired in representing a balance among the interests involved. Fortunately, the interests were not really competitive, and a solution has been found by consent. The Durham colleges retain their original endowments, and remain constituent colleges on the model of the old universities. A new Senate is established, elected in equal shares from Durham and Newcastle, which assigns the conditions for graduation, while each division is at liberty to propose for the approval of the Senate independent courses for the same degree. Thus the degree of B.A., which has hitherto been reserved to students from the Durham colleges, will now be open to students from Newcastle as soon as an approved course is established, and it is hoped that this will lead to a considerable development of Armstrong College upon the arts side, hitherto much stunted in comparison with its equipment for science. The first Vice-Chancellor, appointed on January 25, is Dr. F. B. Jevons, the well-known principal of Hatfield Hall, in Durham. It is much regretted that Sir Isambard Owen, to whose tact the success of the negotiations is largely due, is removed from participation in the first steps of the new plan by his acceptance of the Vice-Chancellorship of the University of Bristol. It will be seen that the new constitution does not bear directly upon the interests of science, but all scientific men will feel that it is an indirect step of the greatest importance to develop thoroughly the arts faculty of a scientific college, and that the added weight of the two Newcastle colleges in the councils of the University cannot fail to enhance their general prestige.

---

[1] It may also, perhaps, be worthy of note that Mr. Egerton's calculations (*loc. cit.*) lead him to postulate an element of nearly this atomic weight, namely, 2·9844, although his paper gives no indication as to its character.

The governors of the South-eastern Agricultural College, Wye, have resolved to extend considerably the college buildings, which are at present inadequate owing to the increasing number of students. The proposed extension, which will be ready for the next session in October, will provide extra rooms for in-college students, and will at the same time increase largely the teaching and research accommodation.

The *Times* correspondent at Ottawa states that, as a first step towards the adoption of a system of technical education in Canada, a Royal Commission is to be appointed to report upon conditions in Great Britain, France, Germany, and the United States. Canada has hitherto done little to give a technical training to her artisans owing to the conflict of opinion between the Federal and provincial Governments in respect to jurisdiction.

It is announced in *Science* that Mr. J. Pierpont Morgan has given 20,000*l.* to Yale University, to establish a chair of Assyriology and Babylonian literature in memory of Mr. W. M. Laffan, late editor of the New York *Sun*. From the same source we learn that the directors of George Washington University have announced that they propose to raise an endowment fund of 400,000*l.* Mr. H. C. Perkins, a member of the board, made an initial subscription of 10,000*l.* toward the fund on condition that the sum be raised.

According to the *Revue scientifique*, in 1909 the teaching staff of fifteen French universities was composed of 366 full professors, 102 lecturers, 148 demonstrators in charge of courses of practical work, and 336 assistants. Of these totals, 173 professors, 29 lecturers, 69 demonstrators, and 174 assistant were engaged in pure science. The university grant authorised by the 1910 Budget amounts to 11,679,553 francs for salaries and so on, and 2,229,827 francs for material requirements. These amounts represent an increase over 1909 of 288,086 francs for salaries and 31,000 francs for materials. The increase for salaries includes the first annual grant of 57,000 francs for improving the emoluments of demonstrators in science and pharmacy and of scientific assistants.

The first number of a monthly magazine to be devoted to the discussion of methods for the improvement of the physical and mental conditions under which the work of schools is done has been issued under the title *School Hygiene*. The review is intended for educational workers and doctors, and is published by the School Hygiene Publication Co., Ltd., 2 Charlotte Street, London, W., at sixpence net monthly. To the present issue Prof. H. Griesbach, president of the first International Congress on School Hygiene; Sir Lauder Brunton, F.R.S., president of the second congress; and Dr. A. Mathieu, president of the forthcoming congress in Paris next August, contribute in German, English, and French, respectively, short essays on cooperation in education. The remaining articles deal in an interesting and informative manner with numerous aspects of the health of school children, and when it is added that among the contributors are the headmaster of Eton and Dr. James Kerr, it will be evident that there is a judicious mixture of practical acquaintance with school conditions and of medical knowledge.

The annual statement has been issued referring to the operation of the Rhodes scholarship scheme. After several years' experience, the University of Oxford seems satisfied with the type of scholar sent to Oxford. There were in residence during the academic year 1908–9 179 Rhodes scholars. Of these, 78 were from the colonies, 90 from the United States, and 11 from Germany. At the end of June 33 completed their course, and in October 31 new scholars came into residence. Five were given permission to suspend their scholarships temporarily, while six ex-scholars remain in residence engaged in teaching, research, or special study for examination. The total number of scholars and ex-scholars at the beginning of the new academic year 1909–10 was 178. Of 83 scholars from the United States who completed their course at Oxford, 82 returned to their own country, and one accepted work in England. Of 23 Germans, all returned home except one, who had accepted a teaching post in America. Of 78 colonial students, 12 are still engaged in courses of study preparatory to professions. Of the remaining 66, 51 have either returned already or are about to return to their own countries; four are teaching in England, but looking for colonial appointments in the future; one is for the present engaged in parochial work in England, with the view of service ultimately in his own colony; two have gone to colonies other than their own; three have accepted appointments in India; two, business positions in foreign countries; and three have decided to follow their professions in England. It is interesting to note that, of the total number of scholars, while 16 only took a distinctly classical course in the honour schools, 20 took up natural science, and that mathematics, forestry, and anthropology each attracted a few men only. Jurisprudence and history seem to have been the most popular subjects among the scholars.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 27.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir James **Dewar**: Long-period determination of the rate of production of helium from radium.—Sir James **Dewar** and Dr. H. O. **Jones**: Note on carbon monosulphide. No doubt decomposition is known which results in the direct production of a substance of the composition of carbon monosulphide. We have found that nickel carbonyl and thiophosgene react at the ordinary temperature according to the following equation:—

$$n\mathrm{CSCl}_2 + n\mathrm{Ni(CO)}_4 = n\mathrm{NiCl}_2 + 4n\mathrm{CO} + (\mathrm{CS})_n,$$

to produce a polymerised form of *carbon monosulphide*. The solid products were separated by treatment with water, and the insoluble residue, after drying at 150° C. under reduced pressure, was obtained as a very dark brown or black amorphous solid, which is sparingly soluble in some solvents, such as ethylene dibromide, carbon disulphide, and phenol, to give deeply coloured solutions. The solubility was not sufficient to enable the molecular weights by lowering of freezing point to be determined. The specific gravity of carbon monosulphide is 1·6, and hence its molecular volume is 27·5, while that of solid carbon disulphide is 52·4. A comparison of these values with the corresponding values for solid carbon monoxide (28) and carbon dioxide (28·7) shows that carbon monosulphide is formed from carbon disulphide with considerable condensation. On heating carbon monosulphide no change takes place below 360° C., but at a red heat it gradually decomposes into carbon disulphide and carbon. Carbon monosulphide dissolves in concentrated sulphuric acid to a brownish-purple solution, from which it is precipitated unchanged on the addition of water. It dissolves in alkalies to a dark brown solution, from which acids precipitate it unchanged. Other reactions are being investigated.—Sir W. de W. **Abney**: The extinction of colour by reduction of luminosity. In this paper the author gives the results of reducing the luminosity of all the rays of the spectrum to the point at which they become colourless when compared with white. The white itself varies in hue according to the amount of reduction in its luminosity. No notice is taken of this variation, so some parts of the spectrum do not require so much reduction to match the white as they would do if the white is kept of a uniform hue.—G. W. **Walker**: The initial accelerated motion of electrified systems of finite extent, and the reaction produced by the resulting radiation. The present investigation forms a development of a paper already communicated to the Royal Society (Proceedings, A, vol. lxxvii., p. 260). Its chief aim is to obtain, directly from the fundamental equations of electro-magnetism, a method of dealing with small disturbances from a steady state of motion, and thus avoid possible errors that may arise if one relies entirely on the principle known as that of the "quasi-stationary state." The method is explained in the first six sections, which include the problem of initial uniformly accelerated motion of a charged conductor of finite size, either from rest or from uniform motion in a straight line. It appears that the electric inertia calculated by this method does not always agree with the value obtained from the energy of a steady state. As the results obtained include the case of a conductor of small dimensions, several formulæ are compared with the experiments of Kauffmann on Becquerel rays, and a fair proportion of inertia of ordinary kind is found to be indicated by these experiments. Application of the method to uniformly accelerated linear and rotary motion of insulators has been made. It is found that the electric inertias for linear and rotary motions are the same, provided half of it is located at the centre and half is uniformly distributed over the surface of the spherical body, supposed an insulator. Several sections deal with vibratory motion of electrified systems. Some new features connected with emission and absorption, and dependence of frequency and damping on speed, are indicated.—H. **Thirkill**: The nature of magneto-kathodic rays. In the experiments described a variable longitudinal magnetic field acts upon an electric discharge. The experiments support the hypothesis that the luminous band, which, in a strong magnetic field, follows the direction of the lines of magnetic force and has the kathode for section, consists of slowly moving kathode rays. These have been bent by the magnetic field into the form of a very fine spiral. The charge was detected by using a sensitive galvanometer. On this view, the following facts observed by Villard and Righi are explained:—(1) the magneto-kathodic rays very often appear quite suddenly, and (2) their appearance is accompanied by an increased difficulty in detecting a charge on them; (3) the rays are deflected by an electric field in a direction at right angles to the directions of both the magnetic and electric fields; (4) the distance the rays extend from the kathode depends on the strength of the magnetic field. The conclusion arrived at is that there is not sufficient evidence to prove that the magneto-kathodic rays constitute a new kind of rays.—E. **Cunningham**: The velocity of steady fall of spherical particles through a fluid medium. In view of experimental work on the fall of small spherical particles through air, a discussion is made in this paper of two of the main causes of deviation from Stokes's law for the limiting velocity. The first effect considered is that arising from the radius of the particle being comparable with the mean free path of the air molecules. The following modification of Stokes's formula is obtained:—

$$W\left(1+\frac{1\cdot63\,l}{a(2-f)}\right)=6\pi\mu aV,$$

where l is the mean free path of the molecules of air, W is the weight, a the radius, and V the limiting velocity of a falling particle, f being a fraction depending on the nature of the surface of the particle, being unity for a perfectly smooth elastic surface. For most actual cases f probably lies between 0 and $\frac{1}{2}$. The formula agrees with Zeleny's recent experimental verification that for particles of radius greater than 10^{-4} cm. the deviation found is not large. The second effect discussed is that due to the simultaneous presence of a large number of particles distributed throughout the fluid, assumed in this case to be a continuous viscous medium. A formula is obtained which indicates that, as the number of particles per unit volume increases, the limiting velocity diminishes. The following table gives the ratio of the estimated limiting velocity (V^1) to that given by Stokes's law for different values of the ratio of a, the radius of the particle, to b, the mean distance between the centres of two adjacent particles:—

b/a	1·63	2·45	3·26	4·08	4·90	5·71	6·50	7·35	8·16	16·3	24·5	∞
V^1/V	7·29	3·02	2·10	1·76	1·57	1·46	1·38	1·32	1·28	1·14	1·08	1

—Dr. S. B. **Schryver**: The photochemical formation of formaldehyde in green plants. On the addition of phenylhydrazine hydrochloride, potassium ferricyanide and hydrochloric acid to solutions containing formaldehyde, a fuchsine-like colour is developed, by means of which the aldehyde, when present in small quantities, can be estimated. The reaction can also be applied to the estimation of formaldehyde when present in combination in such substances as oxymethylene tetramine, if the reaction mixture be boiled after addition of the phenylhydrazine reagent and before the addition of the ferricyanide and hydrochloric acid. By means of this method, formaldehyde can be readily detected when present to the extent of only one part in a million. The reaction has been applied to demonstrate the presence of the aldehyde in chlorophyll prepared from grass gathered after some hours of sunshine. The chlorophyll was extracted by alcohol, the solvent was then evaporated off, and the residue re-extracted with ether. In the product thus obtained, the presence of the aldehyde could be demonstrated after warming it or allowing to stand for some hours with the phenylhydrazine reagent. The ethereal solution of chlorophyll, on standing for some days, yielded a product which no longer showed the formaldehyde reaction. Formaldehyde was absent also in a sample of chlorophyll prepared from grass on a foggy morning. By exposing films of such aldehyde-free chlorophyll to sunlight in the presence of moist carbon dioxide, the formaldehyde reaction reappeared. Even in the absence of carbon dioxide slight traces could be detected after exposure to sunlight; in this case the carbon dioxide is apparently formed by photochemical decomposition of some constituent of chlorophyll. In the dark, formaldehyde was never generated. The results indicate that formaldehyde, as it is formed in plants, enters into somewhat stable combination with a constituent of the chlorophyll. Such a methylene derivative will, in the presence of water, undergo only slight hydrolysis, and equilibrium will be maintained in the presence of only a very small amount of free formaldehyde. As this is removed from the sphere of action by polymerisation or otherwise, the chlorophyll methylene derivative will undergo further hydrolysis, with the scission of further small amount of aldehyde. In this way the amount of free formaldehyde present at any moment in the plant can be regulated, and thus the highly toxic aldehyde will never be present in such quantities as to harm the plant.

Faraday Society, January 18.—Dr. F. Mollwo Perkin, treasurer, in the chair.—S. **Field**: The conditions which determine the composition of electro-deposited alloys. Continuing the study of the quantitative composition of electro-deposited alloys, those of copper and silver have been examined. For the electrolyte, a mixture of the double cyanides was again used. Ordinarily, silver is more negative than copper, but the difference in their character is such as would not seem to indicate any difficulty in depositing them simultaneously from a cyanide solution. The composition of the deposits was obtained by dissolving in nitric acid, and estimating the silver as chloride, except where the copper was obviously small, when that metal was determined. When a copper coulometer is in circuit the ratio (R) of the weights of alloy and copper deposited in the coulometer gives a figure from which, under ideal conditions, the composition of the alloy may be determined thus:—

$$\text{Percentage of silver}=\frac{241}{R}(R-2).$$

Experiments soon proved that simultaneous deposition only occurs within very narrow limits. Thus when the metals in the solution are in the proportion of even 1 equivalent silver to 34 equivalents of copper no deposition of copper occurs under ordinary conditions of current density, but when in the proportion of 1 equivalent silver to 100 equivalent copper, simultaneous deposition proceeds more readily.—T. P. **Burt**: The compressibilities of helium and neon. The compressibilities of the two gases were measured between the pressure limits of 850 and 150 mm. of mercury. With the object of determining the lie of the isothermals over this pressure range as accurately as possible, a large number of volume and corresponding pressure readings were made. On plotting pv against p, a straight line was obtained in the case of both gases. Helium was found to obey Boyle's law, the value of pv being independent of the pressure. In the case of neon, pv diminished as the pressure diminished, and the value of $d(pv)/dp.1/pv$ was found to be 0·00105.—Dr. A. C.

Cumming: Gas-washing bottles with a very slight resistance to the passage of a gas. Three forms are described. In one a short side-tube is joined to the inlet-tube of an ordinary washing bottle and bent upwards, so that the gas bubbles passing through it carry some liquid with them, causing constant circulation of same. In a second and more efficient form, the gas passes through a length of 5 mm. tubing, slightly inclined to the horizontal. Below this, and connected to its ends, is a bulb of liquid, so that here again the passage of gas through the tube causes a circulation of liquid. The third form described is a modification of the Richardson wash-bottle, in which the pressure is reduced by lengthening the nozzle through which the gas enters the washing bulb.—Dr. F. Mollwo **Perkin** and W. E. **Hughes**: Studies in the electro-deposition of metals. The authors describe a rotating kathode employed for rapid electro-deposition of metals. It consists of sheet platinum spun up so as to form a narrow thimble, the upper end being open and having a stout iridium wire fused to it. This electrode, which has an active surface of 16·3 cm., is rapidly rotated within a cylindrical platinum gauze anode. In other cases, particularly when graded potential methods are employed, a spiral anode of platinum is rotated within the gauze cylinder, which then functions as kathode. In the potential measurements a cylindrical glass funnel with a glass tube sealed in the side is employed for holding the electrode.

THE NUTRITION OF PLANTS.

Artificial Manures, their Chemical Selection and Scientific Application to Agriculture. By M. Georges Ville. Translated and edited by Sir William Crookes, F.R.S. New edition, revised by Sir William Crookes, F.R.S., and Prof. John Percival. Pp. xxxviii+347. (London: Longmans, Green and Co., 1909.) Price 10*s*. 6*d*. net.

SIR WILLIAM CROOKES and Prof. Percival have revised and re-issued the lectures given by Georges Ville at the experimental farm at Vincennes during 1867 and 1874–5, and originally translated by Sir William in 1879.

"It is only just," he says in introducing the volume, "that its claims to be regarded as a classic and its author's right to the title of pioneer should not be forgotten when many of Prof. Ville's views are so generally adopted that his prescience and acumen are likely to be underrated and his priority unrecognised."

Ville was an ardent supporter of Liebig's views on the nutrition of plants. He was one of the brilliant band of men who at that time were developing and spreading the new ideas; several of the lectures deal with his experiments showing that a full crop can be obtained by supplying the proper food-stuffs in inorganic combination. It is difficult for us now to realise the astonishment with which the older farmers saw crops raised solely by the aid of "chemical" manures without the dung which had always been supposed essential. Lawes and Gilbert showed that it was not; they also falsified the prediction of many of their critics that chemical manures would soon exhaust their land and leave it sterile. Ville went even further, and maintained that artificial manures were unquestionably more remunerative, and afforded, indeed, the only means of keeping up the fertility of the soil. A man who only used dung, he said, must exhaust his land. This is the characteristic note of a great part of the book.

The chemical manures were compounded on a definite plan. For each crop one of the three constituents nitrogen, potash, and phosphoric acid was found to be more necessary than the rest, and was therefore called the dominant constituent. Thus nitrogen was the dominant constituent for cereals and beetroot; potash for potatoes and vines; calcic phosphate for the sugar-cane; there was no dominant, however, for flax. An excess of the dominant constituent was always added to the crop manure.

Great stress was laid on the fundamental differences in nitrogen nutrition between leguminous plants and cereals; nitrogenous manures are not necessary for the leguminosæ, whilst they are for other plants. M. Ville had played a very prominent part in the great controversy that continued during many years as to the source of nitrogen in plants. It seems to have been begun by Priestley, who stated that a plant of *Epilobium hirsutum*, placed in a small vessel, absorbed during the course of a month seven-eighths of the air present. He therefore concluded that plants assimilated nitrogen, but this view was soon controverted by Ingenhousz, de Saussure, and others, and was for a time disposed of by the classical experiments of Boussingault. Ville, however, revived it, and his experiments, begun in 1849 and described in two very beautiful volumes, "Recherches expérimentales sur la Végétation" (1853 and 1857), appeared to show that all the plants examined, rape, wheat, barley and maize, actually did take some of their nitrogen from the air. Somewhat later, Lawes, Gilbert and Pugh repeated the experiments but failed to confirm the result. They even used his experimental vessels, which are still to be found among the treasures of the Rothamsted laboratory.

It is not our intention to discuss this discrepancy in the light of subsequent discoveries; we need only point out that Ville was perfectly correct so far as the leguminosæ are concerned, and that his error with regard to other plants did not lead him astray in making up his manures.

No value was placed upon soil analysis; "at the present time the most laborious analysis is not able to throw light upon the most vital and essential question of practical agriculture." The deficiencies of the soil are determined by trials with the plants themselves. Plots are directed to be laid out in the field as follows:—

(1) With the normal (*i.e.* complete) manure; (2) normal manure without nitrogen compounds; (3) normal manure without phosphates; (4) normal manure without potassium compounds; (5) normal manure without calcium compounds; (6) unmanured.

This is substantially the scheme now adopted in almost every county in England. Under his supervision large numbers of such experiments were carried out in France. Some of the results are astonishing. In one case a plot receiving 32 tons of farmyard manure per acre gave a crop of 14 bushels per acre whilst a neighbouring plot receiving half a ton of chemical manure per acre yielded 36 bushels. There was a loss of about 19*l*. in the former case and a gain of about 17*l*. in the latter.

Ville's main thesis that crops can be grown with chemical manures had already been demonstrated by Lawes and Gilbert, with whose names it will for ever be associated in England, and is now a commonplace in practical agriculture. His view that chemical manures are in all circumstances better than dung has not survived. He made no allowance for the wonderful effect of the organic matter present in the dung in improving the texture and water-holding capacity of the soil—an effect not shown at all, or even shown in an adverse sense, by artificial manures. When we remember how large a part of the farmer's labour is devoted to cultivation it is easy to understand his preference for dung. Indeed, on many soils addition of organic matter is absolutely indispensable. Further, it may be doubted whether we possess even yet the data necessary for working out the relative costs of farmyard and artificial manures in the complex conditions of modern farming, with its inter-dependence of crops and of live stock and its fluctuating financial equilibrium. Nor have Ville's formulæ for compound manures survived. The amount of food a plant requires is known to be modified by the water supply, the temperature, and the general soil conditions. It is clear that no one formula could possibly suit all cases; indeed, we might sum up the difference between Ville's views and those current now by saying that Ville regarded the supply of plant food as the dominating factor in determining fertility, whereas we now know it is only one of several equally important factors.

The lectures are interesting to read and must have been delightful to hear; they will form valuable material for the historian of agricultural science when he arises, not only by reason of the views set forth, but also because of the numerous balance-sheets and statements of costs. For their historical interest also they will be read by the serious student of agricultural chemistry, who indeed is already attracted to them by the fact that they have interested Sir William Crookes.

Certain alterations have been made in the text, so that the lectures are not quite in their original form. The editors have preferred to do this rather than to make corrections in footnotes, a plan which, if more cumbersome, would have had the advantage of preserving the historical value of the book. A chapter has also been added on the fixation of atmospheric nitrogen. All fixation methods attract much popular attention, while the electrical method first indicated by Sir William Crookes is already a rich and promising addition to our agricultural resources.

E. J. RUSSELL.

MODERN CHEMISTRY.

Handbuch der anorganischen Chemie. Herausgegeben von Dr. R. Abegg und Dr. F. Auerbach. Dritter Band, Zweite Abteilung. Pp. xii+921. (Leipzig: S. Hirzel, 1909.)

THIS stately volume of more than 900 pages treats of the elements of the fourth group of the periodic system, namely, C, Si, Ti, Ge, Zr, Sn, Pb, and Th. It opens with an excellent comparative summary by Abegg and Brauner of the general chemical and electrochemical relationships of the members of the group. Then comes a truly magnificent monograph on carbon by Weigert, covering 276 pages, with a literature-index containing 1307 references. It would be quite impossible in a short notice such as the present to give any adequate idea of the masterly manner in which the author has dealt with his great subject, so that a few references must suffice. In dealing with the allotropic forms of carbon, the usual purely descriptive account is followed by an extraordinarily interesting discussion of the energy- and stability-relationships, in which the researches of Schenck and Heller, and of Smits, are dealt with. The author also applies Nernst's theorem to the problem of the transition-point between diamond and graphite, but an arithmetical error appears to have crept into his calculation here.

The highly important theoretical and experimental researches on the formation, dissociation, and stability-relationships of the hydrocarbons are treated very fully, Nernst's thermodynamical theorem serving here (as elsewhere) as a basis for calculation. A good account is also given of Bone's work on the oxidation of hydrocarbons.

Under the heading of "Flame" the author does not fail to give us a lucid account of the modern work of Haber and his collaborators, whilst the subject of explosions introduces the reader to the work of Mallard and Le Chatelier and Dixon.

The chemistry of carbon has afforded the author a splendid opportunity of familiarising the chemist with the thermodynamics of high-temperature gas equilibria, and he has taken good advantage of it. The treatment of such highly important subjects as the dissociation of CO_2, the $C—CO_2—CO$ equilibrium, the water-gas equilibrium, and various heterogeneous gas-equilibria, such as $C—N—C_2N_2$, $C—S—CS_2$, $C—NH_3$ $HCN—H$, is excellent. The treatment of these matters brings the author to the discussion of such fundamental questions as the free energy of carbon combustion and the quantitative measure of the reducing power of carbon and its simpler gaseous compounds. What a vista is opened here to those who have the eyes to see and the minds to understand! It is a painful reflection to realise how soon all this will be as familiar to the trained modern German chemist as the laws of Dalton and Avogadro, whilst the progress of scientific chemistry in this country is still retarded by the false prophets who are affrighted by the sight of an algebraical symbol, and grievously lament the advance of physical chemistry.

There is an excellent and suggestive account of photochemical plant synthesis, and of the free-energy changes involved in biological metabolisms.

The heterogeneous equilibria presented by solid CO_2 in its various forms, and the ionic dissociation of aqueous solutions of carbonic acid, are well treated. More technical questions, such as the manufacture of coal gas, the calorific power of fuels, and the light efficiency of burning oils, come in for their share of discussion.

Enough has been said to give some idea of the scope and method of this splendid monograph. It is to be sincerely hoped that English chemists will carefully study it.

The next article (by Grossmann) deals with silicon and its compounds, and is full of interesting things. As befits the theme, a very full account is given of SiO_2, the silicic acids, and the silicates. Here we find an excellent *résumé* of Tschermak's interesting researches on the constitution of the silicates, together with the criticisms of Jordis, van Bemmelen, and Mügge thereon.

Another very interesting section deals with the work of Vogt, Doelter, and Allen and Day on the silicate melts.

Silicon is followed by a compact and up-to-date article of twenty pages on glass, by Schaller.

Titanium is dealt with by Jacoby. Here we find a very full discussion of the important work of Diethelm and Foerster on the electrochemical reduction of acid titanic sulphate solutions.

Germanium and zirconium are well presented by

G. Rudorf and R. J. Meyer respectively, after which comes, if we may so express it, another *pièce de résistance* in the shape of a splendid article on tin from the pen of Ernst Cohen. In this is to be found a very scholarly and learned essay on the early history of this metal, and an exhaustive and beautifully illustrated account of that romantic and fascinating subject, the allotropic forms of metallic tin. As is well known, the chemistry of tin owes much to the researches of Cohen, and we are not disappointed in expecting to find his treatment of the subject exceptionally full and interesting.

Tin is followed by a long monograph on lead, by Ahrens and Pick. Here again the reviewer feels it his pleasant duty to bestow unstinted praise. The article opens with a very full account of the metallurgy of lead. The fundamental researches of Schenck and Rassbach on the heterogeneous equilibria between PbS, $PbSO_4$, PbO, and SO_2, are dealt with, however, under PbS. The electrochemical relations between lead and its ions are clearly and fully explained, including the work of Cumming on the oxidation-potentials of PbO_2. The chemistry of lead and its compounds offers many interesting points, all of which afford the author good opportunities for demonstrating the power and scope of physico-chemical methods of attack. Amongst these may be mentioned the work of Pleissner and Auerbach on the basic sulphates and carbonates of lead, the work of Pleissner and Auerbach and of Dolezalek on the solubility of $PbSO_4$ in water and sulphuric acid solutions, the work of Lewis on the solubility of $Pb(NO_3)_2$ in solutions of KNO_3 and $NaNO_3$, the stabilities and mutual relations of the oxides of lead, &c. In connection with the latter subject, the author has, however, missed the work of Brislee on Pb_2O.

In dealing with the demonstration by Allmand and Denham of the existence of *monovalent* lead ions, the author suggests by way of criticism that the experiments alluded to could be explained in another way, *i.e.* by the assumption of the existence of complex kations of the formula $Pb_2^{\cdot\cdot}$. These might still be *monovalent* ions, and the assumption by Allmand and Denham of the simpler formula $Pb^{\cdot}$ remains the best explanation until the existence of such complex kations is experimentally demonstrated.

After lead comes an article on the lead accumulator, by Mugdan. Needless to say, the article is chiefly concerned with the thermodynamic theory as worked out so beautifully by Dolezalek, although due mention is made of the early work of Faure, Planté, Gladstone and Tribe, and Streintz. This excellent article may be earnestly commended to the attention of electrical engineers. The usual English treatises on the lead accumulator consist of constructive details plus a little perfectly useless juggling with chemical symbols.

Thorium, the last member of the series, is dealt with by R. J. Meyer. Here is to be found an excellent account of the manufacture and optical (selective radiation) theory of the incandescent gas mantle.

Throughout the book colloidal states of matter are treated by Lottermoser. Of especial interest are the articles dealing with those classical examples, silicic and stannic acids.

Atomic weights are dealt with by Brauner in masterly fashion.

On laying down this wonderful volume, one cannot help feeling, as in the case of its predecessors, that Abegg's great undertaking marks the beginning of an era, the era of scientific inorganic chemistry. One realises with a spirit of rejoicing that inorganic chemistry has become a rational science of which every chemist may justly feel proud. The day of the why and the wherefore has dawned. One may beg leave to reason in inorganic chemistry as in other exact sciences. What middle-aged chemist of the present day can forget the inorganic chemistry of his youth, with its alchemistic recipes, its dry lists of formulæ, and its grim determination to explain *actions* by means of symbols invented to describe the *static* facts of composition? It was in truth little more than a sort of glorified black magic. Even at the present day there are not wanting signs that this sort of thing is not entirely dead. How many of our young graduates could read and thoroughly understand the pages of Abegg's "Handbuch"? One would not like to hazard an answer to that question, and yet on that answer depends very largely the hope of future progress. The methods of physical chemistry have converted the empiricism of the older inorganic chemistry into the rational science of to-day. The same tremendous transformation is fast approaching in the sphere of organic chemistry. Other things being equal, the victory lies with those who can best command the keen-edged weapons of physics and mathematics.

F. G. D.

TWO MAMMAL BOOKS.

(1) *The Grizzly Bear: the Narrative of a Hunter Naturalist, Historical, Scientific, and Adventurous.* By W. H. Wright. Pp. x+274; illustrated. (London: T. W. Laurie, 1909.) Price 7*s*. 6*d*. net.

(2) *The Animals and their Story.* By W. P. Westell. Pp. 322; illustrated. (London: R. Culley, n.d.) Price 5*s*. net.

(1) A VERY cordial welcome should be extended to Mr. Wright's intensely interesting volume, which has an exceptional value as embodying the experiences and opinions of a man who has hunted the great bear of the Rocky Mountains at a time when it was more numerous than is at present the case. The author tells us that he was born in New Hampshire in 1856, and that some time after 1883 he commenced bear-hunting during such intervals as could be spared from his business. Later on, in 1889, hunting became his profession, and he was seldom long away from the woods, his trips being sometimes made alone, but more frequently with companions who desired to be initiated into the mysteries of bear-stalking, and were able and willing to pay for the privilege.

"In the beginning," he writes, "I studied the grizzly in order to hunt him. I marked his haunts and his habits, I took notice of his likes and dislikes. . . . And then at last my interest in my opponent grew to overshadow my interest in the game. . . . I came to hunt him in order to study him. I laid aside my rifle. It is twelve years since I have killed a grizzly. Yet in all those years there is not one but what I have spent some months in his company. And then (alas! that it had not been sooner) I undertook to photograph him."

The book commences with an account of the early history of the species, as given by Lewis and Clark and subsequent writers; and the author discusses whether the animal ought to be called the grisly (meaning fierce) or grizzly (grey) bear. He decides in favour of the latter, although admitting that Lewis and Clark used grisly (perhaps in the sense of grey), and that Ord gave the name *horribilis* as the Latin equivalent of grisly in its proper sense. In our own opinion this usage ought to be followed.

To follow the author through his bear-hunting and "bear-snapping" experiences is, in our limited space, impossible, and we must be content in directing attention to the beauty and interest of his photographs of grizzlies in their native wilds. Very interesting, too, are his pictures of the slots of the grizzly and the black bear, showing how widely they differ from one another. The front claws of a grizzly are generally described as being whitish and nearly straight; but the author shows that the latter definition is incorrect, and that they are better described as narrower and less sharply curved than those of other bears.

The book is teeming with interest, and may be cordially recommended to naturalists and sportsmen as a trustworthy account of a disappearing species.

(2) Commendation of a like nature can, we regret to say, scarcely be accorded to the second of the two works forming the subject of this notice. Mr. Percival Westell is a voluminous writer on the fauna of Britain and various groups of invertebrates, but has hitherto, we believe, not tried his hand on mammals as a whole. In the present volume he has attempted to give an account of a selection of the more interesting types of the class, especially those represented in the London Zoological Gardens, arranged according to the nature of their environment, and illustrated with a number of photographs and coloured plates. The photographs are for the most part worthy of all praise, while the execution of the coloured plates is also good, although it is a pity that in some instances—notably the one of the wapiti—the artist was furnished with such poor models.

The volume is confessedly a compilation, largely made up of extracts from the writings of Mr. Selous and two well-known works on natural history—one, by the way, somewhat out of date. When he confines himself to direct extracts from these Mr. Westell does not wander far from the right path, but when he draws material from his own mind the result is disastrous. We are calmly told, for instance, on p. 245, that, in consequence of the domestication of the species, there are probably no wild yak in Tibet; while from the text and figure on pp. 245 and 246 the author would appear to be labouring under the impression that the cows are hornless. On p. 139 we are informed that it is the brindled, instead of the white-tailed, gnu that is verging on extinction; while from the statement on p. 314 it would appear that the author is quite unaware of the existence of the white rhinoceros in Lado and the Bahr-el-Ghazal, where it is not in the least danger of extermination. Striped elands (p. 174) are said to occur in northern Africa, where there are no elands at all; Grévy's zebra (p. 114) is stated to have been discovered by Grant and Speke; and the roebuck is affirmed to be a near ally of the muntjac (p. 113). As instances of carelessness we may mention (p. 267) *Kabern* for *Kaberu*, and (p. 220) *arin* for *arui*. To quote Mr. Ingersoll (p. 242) as the authority for the absence of deer from Ethiopian Africa is about equivalent to referring to Sir Robert Ball as sponsor for the rising of the sun to-morrow morning; while the statement on p. 304 with regard to the distinctness or identity of the European and American beavers is absurd.

Many other blunders and instances of carelessness might be quoted, but the foregoing are sufficient to indicate the untrustworthy nature of Mr. Westell's book.

R. L.

RELIGIO PHYSICI.

Man and the Universe: a Study of the Influence of the Advance in Scientific Knowledge upon our Understanding of Christianity. By Sir Oliver Lodge, F.R.S. Pp. viii+356. (London: Methuen and Co., n.d.) Price 7s. 6d. net.

IN this vigorous and attractive work Sir Oliver Lodge has gathered into a more or less systematic whole his well-known views upon the relation between science and religion. The result is a "Religio Physici" which recalls its famous prototype as much by contrast as by similarity. Sir Oliver Lodge, like Sir Thomas Browne, is at once a man of science and a sincere and candid friend to religion, but his apology for this position is far from a mere demonstration that a whimsical temperament can (by a *credo quia impossibile est*) hold incompatibles in conjunction. Nor does he follow the dangerous precedents of later apologists, who have strained analogies to prove that science and orthodox Christianity, so far from being at loggerheads, are really in perfectly amicable agreement. There is, admits Sir Oliver, "an outstanding controversy" between orthodox men of science and orthodox theologians, "although active fighting has been suspended." The reason for this controversy is "that the attitudes of mind appropriate to these two classes" are "at present fundamentally diverse." Such being the case, the only hope of reconciliation lies in the admission on the part both of man of science and of theologian that neither is in occupation of the sole point of view from which truth is visible. In particular, the man of science must learn

> "that it is a sign of unbalanced judgment to conclude, on the strength of a few momentous discoveries, that the whole structure of religious belief, built up through the ages by the developing human race from fundamental emotions and instincts and experiences, is unsubstantial and insecure."

In place of such partisan exclusiveness we must cultivate the conviction that science and religion both contain systems of truth which must ultimately prove to be congruent: "the region of true religion and the region of completer science are one."

In pursuance of this plan of reconciliation, Sir

Oliver Lodge once more presses upon the physicist his favourite argument (formerly urged in these columns) that the universal operation of formal laws such as the conservation of energy, still leaves room for intelligent "guidance and control"—and may even be compatible with the efficacy of prayer. Further, he recommends more serious attention to the better established data of "psychical research," and the hypotheses as to the nature of human personality based upon them—since both data and hypotheses have an important relation to certain contents of orthodox Christian doctrine. To the theologian he commends a more frank acceptance of the established results of scientific inquiry, counselling him to base his system neither on facts of a negative kind (such as the biologist's present inability to trace the origin of life) nor on single historical events of an alleged miraculous order, but to found it upon the ever-present facts of human nature and experience. The synthesis of this "completer science" with this "true religion" would yield what the author regards and defends as an anthropomorphic pantheism.

Sir Oliver Lodge is evidently aware that professed theologians will regard his work in their department with little more than the politeness due to a distinguished amateur. It is to be feared that the professed philosopher will adopt a similar attitude towards his metaphysics, while, no doubt, there are physicists who remain unconvinced by the doctrine of "guidance." Nevertheless, the book will be read with approval and profit by a great many persons of moderate opinion, who, in matters that affect life as a whole, are disinclined to submit to the tyranny of the departmental expert. Moreover, it will be commended to most readers, not only by the writer's characteristic fairness and sincerity, but also by a tenderly reverent and sometimes eloquent treatment of certain topics unsuitable for specific discussion in this journal.

The reviewer has to express his regret for the late appearance of this notice, for which he alone is responsible. T. P. N.

MATHEMATICAL PRINCIPLES AND PRACTICE.

(1) *Descriptive Geometry.* A Treatise from a Mathematical Standpoint, together with a Collection of Exercises and Practical Applications. By Prof. V. T. Wilson. Pp. viii+237. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 6*s*. 6*d*. net.

(2) *Practical Arithmetic for Schools.* By W. G. Borchardt. Pp. viii+445+lxxvi. (London: Rivingtons, 1909.) Price 4*s*. 6*d*.

(3) *The Calculus and its Applications.* A Practical Treatise for Beginners, especially Engineering Students. By R. G. Blaine. Pp. ix+321. (London: Archibald Constable and Co., Ltd., 1909.) Price 4*s*. 6*d*. net.

(1) PROF. WILSON'S "Descriptive Geometry" is "a treatise from a mathematical standpoint." The author believes that the subject has "suffered mutilation in the interests of short cuts to immediate practical uses," and his aim has been to "refrain from any attempt to hold the student's interest by clothing a few principles with some immediate practical application." From this point of view he has succeeded in producing a sound and excellent work. In the chapters on the point, line and plane, the theorems and principles on which the constructions are based are formally and clearly set out. The scope of the book embraces a general classification of lines and surfaces, including developable surfaces such as the cylinder, cone and convolute; warped surfaces like the hyperbolic paraboloid, conoid, and helicoid; and double curved surfaces, for example, the sphere, ellipsoid, &c. The projections, tangencies, intersections and developments of these surfaces are dealt with. As each new problem is stated, its general solution is first given with reference to the principles involved, and this is followed by a drawing showing the full construction for a particular case; this seems to be an admirable method, conducive to clear thinking and a thorough grasp of the subject.

A collection of exercises and some suggestions for practical applications are provided in the last chapter, and the volume closes with a very complete index. Anyone who has mastered the contents of this book will have no difficulty in applying his knowledge to any practical cases that are ever likely to arise.

(2) The arithmetic by Mr. Borchardt will rank with the best of the recent text-books on the subject. It follows the latest developments, which are now so well known as to render superfluous any detailed description. The requirements of the counting-house, workshop, and laboratory are fully met. The exercises are abundant, carefully graded and of diversified interest, and test papers and copies of recent examination papers are provided. The book is divided into two parts, which may be obtained separately or under one cover, and with or without answers. This school arithmetic cannot fail to give full satisfaction wherever it is used.

(3) "The Calculus and its Applications," by Mr. Blaine, covers a considerable extent of ground, including the differentiation of hyperbolic functions; successive and partial differentiation; maxima and minima of functions of one and two variables; Taylor's theorem; integration by analytical, mechanical and approximate methods; double and treble integrals; differential equations, solutions by symbolic methods; and a chapter on periodic functions and harmonic analysis. The subject is not developed by the author in any very strict logical sequence, and the book is not suitable for beginners working without the aid of a teacher. The principal feature of the work is the large collection of examples illustrating the application of the calculus to practical problems in mensuration, physics, mechanics, and engineering. These are extensively used in the text to explain the significance of the symbols and the operations of the calculus, and are provided at short intervals as exercises for the student. Teachers will value the book mainly on account of the interest and variety of these practical problems.

OUR BOOK SHELF.

A Primer of Statistics. By W. Palin Elderton and Ethel M. Elderton. Pp. viii+86. (London: A. and C. Black, 1909.) Price 1*s*. 6*d*. net.

In his Herbert Spencer lecture of 1907, Sir Francis Galton outlined a suggested course of "Object-lessons in the Methods of Biometry," adapted to persons with no mathematical knowledge. The course was to consist of five lessons, the first to introduce the learner to the idea of variability and the median, the second to deal with the scheme of distribution (the ogive curve), the third with deviations from the median, the fourth with frequency curves (including the arithmetic mean and the standard deviation), and the fifth with correlation.

The present little volume owes its genesis to this suggestion of Sir Francis Galton, who contributes a short preface, and it follows very much the lines he laid down, with the addition, however, of a chapter on probable errors. The style is for the most part very simple, and the volume should be of real service to biological students and others who desire to obtain a general idea as to the meaning of the terms used in modern statistical methods. A few statements seem, however, to be open to criticism. The student ought not to conclude that "shells possess a mid-length (or median) which is constant in different samples" (p. 6) when he has only examined *two* samples. It is hardly correct to state that "when the difference between two means exceeds three times the probable error, then it is considered to be certain that the difference is significant" (p. 79); it is merely moderately likely. Finally, while it is true that the theory of errors of sampling "depends on the assumption that the things dealt with have been taken at random" (a word which does not appear to be defined), we cannot agree with the unqualified statement that "the collection of statistics in any other way is sheer waste of time," nor that "it is far better . . . to take 5000 or 6000 cases at random . . . than to take 50,000 which are specially chosen" (pp. 82–3); the contrary, indeed, may often be the case.

In the first chapter, we also suggest, it would be better to use longer series as illustrations; Figs. 2, 3, and 5, especially, hardly suggest the true form of the "ogive" to anyone who is not prejudiced by a wider experience than the readers of this book are assumed to possess, and scarcely justify the statement made on p. 6 as to the form of the curve. A second edition of this little volume is sure to be called for, as it fills a distinct gap in statistical literature, and the points mentioned might receive consideration.

All About Ships and Shipping: a Handbook of Popular Nautical Information. By Commander R. Dowling, R.N.R. With a Preface by Commander W. F. Caborne, C.B., R.N.R. Third edition, revised. Pp. xvi+429. (London: Alexander Moring, Ltd., 1909.) Price 5*s*. net.

This is the third edition of a handbook of popular nautical information. It has been compiled by a seaman, and is intended largely, if not chiefly, for the use of general readers. At the same time, it contains much which will interest sea-going folks. It claims to be corrected up to date, but in some sections this can hardly be said to have been accomplished. This is particularly true of information given in regard to warships. For instance, the short chapter dealing with submarine boats does not go beyond the "A" class, whereas last year the "D" class had been reached. The latest developments in battleships are better dealt with, but the inevitable compression which has to be accepted in a book of very moderate size dealing with a great mass of miscellaneous information has resulted in meagre descriptions of types of ships both in war fleets and in mercantile marines. No pretence at originality is made by the author. His task has been one rather of collection and compression of information, and the attempt is, on the whole, fairly successful. The book would prove a pleasant companion to people taking long sea-voyages or short pleasure cruises who desired to identify vessels of different nationalities and different mercantile lines of steamships, or who wished to understand something of the *technique* and vocabulary of the seafaring profession.

In any future edition of the book Commander Dowling would confer a favour upon his readers if references were given which would enable anyone so desiring to turn to larger and authoritative works bearing on the very great number of subjects treated, many of which are necessarily described by him in barest outline. It must not be understood that Commander Caborne fails to acknowledge his indebtedness to others for facts and information; the only fault is that no systematic references are made to places from which information has been drawn. If he introduced another appendix dealing with the bibliography of ships and shipping, it would certainly be welcomed by those who take an interest in maritime affairs, and desire fuller information than can be expected to be found in a pocket book.

Van Nostrand's Chemical Annual, 1909. Second issue. Edited by Dr. J. C. Olsen. Pp. xii+580. (London: Constable and Co., Ltd.) Price 12*s*. 6*d*. net.

The first edition of this "Annual" was published in 1907, and was reviewed in Nature of January 23, 1908. The second issue, which has recently come to hand, has been increased in size by some eighty pages, and contains a considerable amount of new matter, including a table of the physical constants of the alkaloids, by Dr. A. Seidell, and a similar table for the essential oils, by A. E. Secker, who has also revised the tables on fats and oils. Prof. Parr's recently calculated table of the densities of carbon dioxide has been inserted, and also a table showing the melting points and the composition for a number of fusible alloys.

The table of gravimetric factors and their logarithms has been entirely re-calculated on the basis of the international atomic weights for 1909, which involved an unusually large number of alterations. The review of chemical literature and the list of new books give the titles of all important publications which have appeared since the first issue.

The publishers have, we think, been well advised in abandoning the attempt to present a fresh issue every year. Although important alterations in the recognised constants are made from time to time, the majority hold good for long periods, and there cannot be many chemists who would care to purchase a fresh volume of tables every year for the sake of the limited number of alterations that may be made. It appears, indeed, to the writer that the interval between successive issues might with advantage be extended to four or five years, so as to avoid burdening the bookshelves of the purchaser with a number of volumes in which the same tables are of necessity repeated again and again. The attempt to combine tables of reference with reviews of current literature can only be expected to achieve success through a compromise of this character. L.

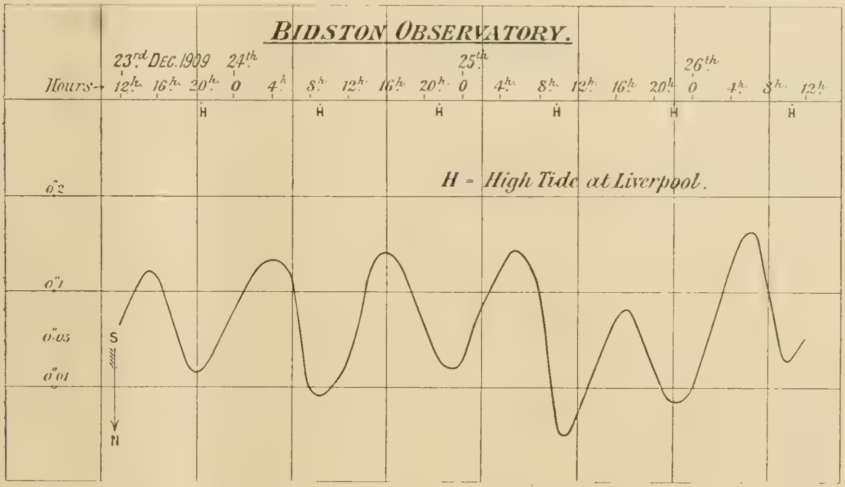
LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Surface Deformation and the Tides.

FOUR years ago I installed in a cellar beneath the Victoria Club, at Ryde, an astronomical level. It was oriented at right angles to the shore-line, only a few yards distant. At the time of high water I found, contrary to my expectation, that the strand, rather than sinking, rose upwards. This I attributed to the tide backing up underground drainage beneath the land, which in consequence bulged upwards. Sir George Darwin, however, makes the suggestion that my observations might be explained on the assumption that the load of water in the English Channel on the south of the Isle of Wight might reverse the effect of a smaller body of water in the Solent on the north side.

I was enabled to make a second attempt to measure the changing slope along a coast in consequence of tidal influences through the kind cooperation of Mr. W. E. Plummer, the director of the Bidston Observatory. This observatory is situated near Birkenhead, about one and a half miles from the sea. The instrument is a slightly modified form of a British Association type of seismograph. It consists of a horizontal boom, 2 feet in length, carrying a weight of 6 lb. At the outer end of the boom there is an extremely light lever, which multiplies the movement of the boom eight times. This, which is a peculiar feature of the apparatus, was designed by my assistant, Mr. Shinobu Hirota. The outer end of this pointer moves above a surface of bromide paper driven by clockwork. A displacement of the image shown on the paper through a distance of 1 mm. corresponds to the displacement which would be obtained were the stand of the pendulum tilted through an angle of 0·08″. The objects of this installation are two-fold, first, to record tidal effects, and, secondly, to pick up minute movements which other types of seismograph seldom record. The accompanying figure shows the tidal effect, which varies with the height of the water, the ebb, and the flow.



The movement of a Horizontal Pendulum at Bidston, December 23–6, 1909. The bob moves to the North with a rising tide. Scale $\frac{1}{16}$ in. = 0·01 second of arc.

At high tide the bed of the Irish Sea is depressed, and the steepness of the bounding shores is increased. The buildings in towns along sea-boards twice a day are tilted seawards. When the tide flows out these movements are reversed. The deflection of the pendulum by tidal load and attraction, although greater than might be expected, is, however, very small. At Bidston it is about 0·2″, or 1 inch in sixteen miles.

JOHN MILNE.

Shide, Isle of Wight, January 24.

A Possible Identification of Comet 1909e.

HERR EBELL has recently determined approximate elliptic elements for this comet.

These elements bear some resemblance to those of comet 1890 VII. Spitaler, which has a period of 6·373 ± 0·01 years, and has not been seen again.

Comet Spitaler had a perihelion distance of 1·8 and an aphelion distance of 5·1. It passes near no other planets than Mars and Jupiter. The small mass of Mars makes the perturbations by that planet of little account.

As comet Spitaler's period is half that of Jupiter, it only approaches Jupiter at alternate aphelion passages. It did not approach Jupiter at its aphelion after its appearance in 1890, but it did approach Jupiter on the following aphelion passage, 1899–1900.

The comet's motion is direct, and it therefore remains in proximity to Jupiter for a considerable time. Its closest approach took place about 1899 November 8, when its distance was about 0·6 and its eccentric anomaly 160°. For more than a year it remained within a distance 0·8 of Jupiter, and the perturbations must have been considerable. If we carry Ebell's orbit backwards, we see that comet 1909e was also near Jupiter in 1899–1900, and there is, therefore, a fair probability of the two comets being the same.

If Ebell's elements were definitive, this identification would have to be given up, for a rough calculation shows that the changes of elements are not in the right direction or of the right magnitude. Ebell's elements, however, merely represent the first attempt to get elliptic elements instead of parabolic elements. They depend on three places only, the first and last being six weeks apart. Herr Ebell himself tells us that the residuals for a fourth observation in the middle of the above-mentioned six weeks amount to a minute of arc, so that it is quite conceivable that the errors of the elements are of the same order as the perturbations by Jupiter.

These perturbations by Jupiter depend upon the exact circumstances of the approach to Jupiter, and these circumstances in their turn may be largely modified by changes in the elements quite small enough to be consistent with the three months' observations in 1889–90. There is, therefore, great uncertainty as to where comet Spitaler should now be, and also some uncertainty as to what are the true elements of comet 1909*e*.

Identity is therefore very far from certain. The excuse for putting forward the present conjecture is the interest that naturally turns upon the question of what becomes of the short-period comets that are only once seen.

P. H. COWELL.

Pleochroic Halos.

IN a recent reference to the subject of pleochroic halos (*Phil. Mag.*, February, 1910) I stated that the outer edge of a corona might present an appearance suggesting an actual accentuation or deepening of the coloration, in accordance with the fact observed by Bragg and others that the ionisation of the α ray increased just before the limits of its ionising range was attained. For certain stages of development of the halo, this observation I have more recently confirmed beyond doubt. Like other structural particulars referred to in my paper, this too becomes obliterated by over-exposure. In one case (in the lithia mica of Zinnwald) a stage of development has been found in which the extreme outer border of the corona is the sole visible part of that structure, the appearance presented being that of a detached, very delicate, ring of perfect regularity surrounding the central halo, a space showing no definitely visible ionisation intervening. The outer ring has a radius of 0·0344 mm., and the inner halo a radius of 0·0191 mm. The outer ring is of about normal radial dimensions; the inner radius is that corresponding to under-exposure to the slower moving α particles. Reference to Bragg's curves (*Phil. Mag.*, September, 1905) will more fully explain.

In the granite of Ochsenkopf, Fichtelgebirge, complex halos will be found very beautifully developed. Some of these conform to dimensions such as might be referred to the α radiations of thorium and its derivatives, others to those of the radium family.

The halos described in my paper, referred to above, are for the most part in a lithia-bearing mica, of a kind which is not correctly included among the Muscovites. The emendation does not, however, notably affect the calculations given. The careful observation of the dimensions of pleochroic halos will, I think, be found of service in distinguishing certain micas—the Biotites from the Muscovites, for instance.

J. JOLY.

Trinity College, Dublin, January 31.

Dangerous Lecture Experiments.

THE explosion referred to by Mr. Power in NATURE of February 3 (p. 399) was probably due to the presence of a trace of moisture in the reacting substances. I had a similar alarming experience some years ago, using precipitated silica without specially drying it.

Moissan ("Traité de Chimie Minèrale," ii., 389), referring to a paper by Ludwig Gattermann (*Ber.*, xxii., 186, 1889), states:—"La réaction ($SiO_2+2Mg=Si+2MgO$) est si violente, d'après cet auteur, que si l'on emploie la silice précipitée, le tube de verre est entièrement déformé, et une partie le la matière est projetée sous forme d'une gerbe de feu." Winkler (*Ber.*, xxiii., 2652, 1890) found that 0·2 gram of a mixture of magnesium and silica in the above proportions heated in a tube closed at one end caused explosion and shattering of the tube. Vigoroux (*Annales de Chimie et de Physique*, xii., 153, 1897) recognised that the explosion is due to incomplete desiccation of the reacting materials.

Few text-books point out the necessity for ensuring the absence of moisture, although most of them point out that the reaction is very rapid and violent. The only book besides Moissan's "Traité" that I have found to give the warning is by an American, Dr. Benedict ("Chemical Lecture Experiments," The Macmillan Company, New York, 1901). Dr. Benedict insists upon the absence of moisture, but does not mention any reason.

This is not the only case in which dangerous experiments have been described and copied from one text-book to another. The collection of hydrogen from the action of sodium upon water is a case in point. Many books describe, with a diagram, the "drowning" of a piece of sodium by means of a special instrument of wire gauze. This *may* be carried out safely in some instances, but, as Newth points out, it is liable to be dangerous. Upon one occasion in my own experience, using a small piece of sodium, an earthenware pneumatic trough was shattered as well as the gas jar used to collect the hydrogen.

It would seem desirable that writers of text-books should obtain some personal knowledge of the experiments they recommend, as young teachers, relying upon the instructions given, might easily cause very dangerous accidents. In neither of the cases cited above would a chemist, unless fairly experienced, be likely to apprehend any difficulty or danger.

E. R. MARLE.

Hartley University College, Southampton.

THE letter of Mr. Power in NATURE of February 3 directs attention to a danger common to the use of any of the metallic reducing agents, and, although well known to a few for many years, it is not at all generally recognised. Even the well-known reaction

$$Fe_2O_3+2Al=Al_2O_3+2Fe,$$

if performed in the way described, is positively dangerous unless all the precaution necessary for a violent explosion be taken.

A very striking lecture experiment is to charge a tiny steel crucible that will contain about one-half up to one cubic centimetre of a mixture of ferric oxide and finely powdered aluminium, and to cover it loosely with a thin sheet-iron cover so as to preserve the contents from water vapour, and then to heat this up in a little furnace made of strong iron gauze covered with asbestos and held rigidly in a retort stand. An ordinary blow-pipe with a foot blower will be sufficient, and the reaction is so violent, as soon as the necessary temperature is attained, that in nearly every case the steel crucible will be shattered into pieces, notwithstanding the lightness of the cover.

The possibly dangerous character of the reduction was noticed by me certainly so long ago as 1896 whilst preparing special qualities of iron experimentally in the South Kensington laboratories, and shown to many persons. Even then it may have been not unknown to other workers with metals, although new to us; and although the mixture was at once respected, and absorbents of heat were used in the charge to moderate the action, I am aware of at least one narrow escape by an operator who wished to verify the observation and used a quarter of a kilogram of the mixture in a crucible heated by a Fletcher oxygen injector furnace, the pieces of which were thrown all over a large room, fortunately without striking any person.

The explanation is simply that the preliminary heating to the temperature of reaction is sufficient to enable the mixture to reach the volatilisation point of the iron by the heat suddenly evolved throughout the mass, and thus there is practically detonation; but it also suggests that some danger of explosion exists should a store of the mixture be involved in a fire, and these mixtures are now in fairly common use industrially.

HENRY C. JENKINS.

The School of Metalliferous Mining (Cornwall),
Camborne, February 5.

The Maintenance of Forced Oscillations.

PLEASE permit me to add a few words to my note on "The Maintenance of Forced Oscillations of a New Type," which appeared in NATURE of December 9, 1909. I stated that when a vibrating fork maintains the vibration of a string by periodically varying its tension, the stationary oscillation maintained may have a frequency of half of, equal to, 3/2 times, twice, &c., of that of the fork, each term in the harmonic series appearing separately by itself, or with one or more of the others conjointly, according to circumstances.

When two or more of the harmonics thus appear conjointly, they generally are not all in one plane of vibration; in other words, one or more appear in a plane which is normal to that of the others, and this can always be secured by a manipulative device. The paths described by any point on the string would in such circumstances be curved figures identical with, or analogous to, the well-known figures of Lissajous.

I send two photographs (Figs. 1 and 2), each only 3 cm. by 2 cm., showing a short length of the string with a brilliant point in the middle of it, when executing such oscillations. The curves shown in them are only two out of a large number that I have observed and photographed, and can be recognised to be both compounds of the first three harmonics in the series mentioned above. It is difficult at first mentally to picture the process by which a tuning-fork executing normal oscillations maintains a string permanently in an oscillation of the type shown in the photographs.

A Tertiary Leaf-cutting Bee.

Although fossil remains furnish us with abundant evidence of the antiquity of many structural characters in animals, and permit us to surmise a like antiquity of certain habits, it is not often that we find preserved the proofs of the latter. The leaf herewith figured, collected in the Miocene shales of Florissant, Colorado, by two of my students, Messrs. Duce and Rusk, shows the work of a leaf-cutting bee. Evidently the specialised and peculiar habit of cutting out pieces of leaf to use in forming the nest was as highly developed, perhaps, a million years ago as it is to-day. The bee itself has also been obtained, and described as *Megachile praedicta*, Ckll., 1908.

Tests for Colour-blindness.

With reference to the article on colour-blindness in Nature of January 27, I should like to point out that advocates of the Holmgren test assume that a person who fails with the wools will fail with coloured lights, and that a person who appears normal when examined with the wools is normal when examined with coloured lights. This was the first point which I proposed to settle when I took up the subject of colour-blindness. I found many varieties of colour-blindness, unimportant from a practical point of view, that failed, and many dangerous varieties of colour-blindness that passed this test. Many absolutely normal-sighted persons are also rejected by the Holmgren test; Germany has officially discarded it for this reason. Within the last fortnight I have examined two dangerous varieties of colour-blindness that passed the Holmgren test with the greatest ease; in fact, the most punctilious examiner would not have suspected that there was anything wrong with their colour sense, but both made the grossest errors with my lantern. The first case could not tell between the white, green, and red lights on trams at a distance of about one hundred yards.

The two factors which seem to be generally overlooked are the great effect of diminishing the intensity of a light in certain cases and the importance of taking into account the size of the image on the retina, that is to say, the number of cones stimulated. A few days ago I examined a normal-sighted man who had failed with the Holmgren test. He put definite browns with the green skein. When I found that he was normal I asked him to name the wools, and he did so correctly. I then asked him why he put browns with green. He replied, "I have been told I am green-blind, and I thought that there was green in those browns which I could not see." When I told him he was quite normal he had not the least difficulty with the test.

Hendon, January 31.

Observations of Halley's Comet.

Readers of Nature may perhaps be interested to know that Halley's comet can now be seen with a good pair of field-glasses. Careful estimates make it almost exactly equal to an eighth-magnitude star.

The best form of instrument is a high-power Galilean binocular, and though the comet does not present any interesting features with such small optical aid, it can be distinctly seen, and distinguished from a star by its nebulous appearance. It is, of course, necessary to know the comet's position fairly exactly before attempting to pick it up. The following are a few of my notes:—

1910, Jan. 8, 12 and 13, Comet faintly seen in 1-inch finder Mag. ± 9·0.
,, ,, 15d. 8h. 45m. Faintly seen in binocular.
,, ,, 30d. 8h. 0m. Steadily seen in binocular.
,, Feb. 3d. 8h. 0m. Found with binocular, eighth magnitude (estimate 8·1).

Zaragoza, Spain, February 5.

Records of the Earthquake of January 22.

Dr. Chree has noted in Nature of February 3 the mechanical effect upon the Kew declination-magnetograph by the earthquake of January 22. Any confirmation of movements of this kind is of considerable value, and I therefore send you this notice of the corresponding effects upon the Stonyhurst magnetographs. All the three elements were markedly affected; the declination magnet was set in oscillation at 8h. 56m. a.m. for five minutes, the vertical force magnet also at 8.56 for about two minutes, and the horizontal force magnet was the most disturbed, commencing at 8.52 and lasting for quite ten minutes, with a maximum displacement of 3·5 mm. against the force of the torsion balance, but it is not clear that there was any swing on the opposite side of the normal position.

The origin of the earthquake remains apparently unknown, but, judging by our Milne seismograph, it was much nearer to us than any of the thirty earthquakes registered here since the instrument was fairly started on active service on July 1, and the proximity may account for the much greater swing of the boom. From the beginning I have claimed the eastern border of the Atlantic for the true region.

Prof. Milne's seismographs at Shide have shown an enduring displacement which has not been produced here.
Walter Sidgreaves.

The Mendel Journal.

In Nature for December 30, 1909 (p. 252), there appeared a review of the first number of the *Mendel Journal*, by "E. H. J. S." He also, in the same review, reviewed the current issue of *Biometrika*. I pass no comment upon the questionable fairness of having two such diametrically opposed journals reviewed by the same person, who, if we may judge by certain statements in the review, is himself a biometrician, or very friendly disposed towards them. I am alone concerned in dealing with your reviewer's misinterpretation and imperfect reading of certain articles of mine written under the *nom de plume* of "Ardent Mendelian." He accuses me of "adopting a tone calculated to be offensive to biometricians," and as an instance he cites the following sentence:—"We may further infer, therefore, that the discipline of the army[1] is very severe, and perhaps this may throw some light upon the constant reappearance of the figure 0·5 in relation to the size of some of its artillery equipment."[2] Your reviewer interprets this as a "serious charge of faking" directed against biometricians. I do not know upon what plan he writes his reviews or whether he reads sufficient of the article he reviews to grasp properly its tone and meaning. Nothing was farther from my intention than to impute want of integrity to any biometrician, notwithstanding some bad examples which they themselves have set, when they deal with Mendelians. Had your reviewer but read a few lines lower down (p. 160) he would have found the following chivalrous sentence, describing them:—

"In some respects it is a very fine army, and it is certainly an imposing one upon parade. It is led, officered and manned by men of transcendent intellect, of whom any country may be proud." And again, on p. 185, in commenting upon Dr. Raymond Pearl's work, I wrote:—"Could we assent to his methods we might commend his results; we can admire his skill as a workman, while lamenting his tools." Then on p. 164, where I criticised the particular way in which Prof. Karl Pearson had set certain questions to a correspondent, I wrote:—"We do not, of course, for one moment suggest that Prof. Pearson desires to be unfair, or that the nature of the question has in the smallest degree influenced the answer. We accept the evidence quite unreservedly."

These quotations are sufficient to show that the articles written by "Ardent Mendelian" were couched in the most courteous tones, and contained even chivalrous acknowledgments of the high ability and integrity of those whose methods of investigation and conclusions he felt bound to criticise. None but the most tender conscience could have misconstrued the particular sentence complained of into a charge of "faking" when the context of the article was taken into account; for how could "any country be proud" of men who "faked"? Your reviewer either could not have read any more of the article than the sentence he quoted, or he must have approached his work in a peculiarly prejudiced frame of mind. I do protest against the unfairness of such treatment. When a writer has been deliberately careful to adopt a courteous tone, it is not fairness to disregard his context—to quote a particular sentence and then to misconstrue it.

This sentence was never intended to convey a charge of "faking," and it simply alluded to the biometrical method of definition in constituting a sort of guide when dealing with investigations in certain problems. Had I intended to impeach the probity of any biometrician my language would have been unmistakable. If your reviewer had but recalled to mind the earlier works of biometricians, he would have remembered a generalisation called "homotyposis," and he would have further recalled that the homotypic average of correlation turned round the figure 0·5. He would also have remembered that this figure was reached by a remarkable process of excluding the parts or organs which were either "too like" or "too different," and this process was based upon an attempted definition by Prof. Pearson—who in my article is alluded to as the Field Marshal—in which he hoped to define the differences between variation and differentiation. This correlation figure of 0·5 was therefore reached by the exclusion of all parts or organs which would otherwise naturally tend to raise or lower the figure, and it was to this process of working by definition and exclusion, as defined by the "Field Marshal" that I alluded when I wrote the sentence which has been, I cannot but help thinking, carelessly misconstrued.

In conclusion, I can only ask that your readers will read the articles and judge for themselves of their courteous tone and fair treatment.

"ARDENT MENDELIAN."

"ARDENT MENDELIAN" is correct in supposing that I am a biometrician; but I am, at the same time, a believer in Mendelism, and I hold that the main aims of the *Mendel Journal* and *Biometrika* are not opposed. To me it appears that people who are studying the same problem by different methods should work in sympathy with one another, and it is for just this reason that I criticised the tone of "Ardent Mendelian," as I was of opinion that it was calculated to make such sympathy difficult.

With regard to the sentence beginning "We may further infer," I still maintain that my interpretation was the most natural one, even after making every allowance for the context; but I accept with the greatest pleasure the author's correction.

E. H. J. S.

[1] Biometrical.

[2] It should be mentioned that the article was advisedly written in terms of martial imagery.

THE INTERPRETATION OF TOPOGRAPHIC MAPS.[1]

THE evolution of maps, and of our ideas regarding their use and function, might be made the subject of an interesting and profitable study. The main object of the early cartographers was to plot down with all attainable accuracy the relative size and position of countries, of towns or of smaller units, and to indicate such natural features as mountains and rivers; roads were added later, and, as the necessity became more evident and geodetic methods improved, the scale was enlarged, while the increasing accuracy permitted additional and minuter details to be introduced. The organisation of national cadastral surveys gave us at last the large-scale contoured maps that, with or without orographic colouring, constitute the highest expression of the map-maker's science.

Upon the basis of the topographic maps, special features of distribution and of activities, such as direction of winds and currents, may be shown, and lines of equivalent development of artificial and natural phenomena, such as isobars and all the other "isos," may find expression. Of these the topographic map takes no account; there has, however, with progress of geographical and geological methods, come a new way of looking at and interpreting a topographic map, so that it is made to disclose not only much that is hidden from the ordinary user, but even more than was recognised by the surveyor who made it. The old reading of a map was an appreciation of the morphology of a piece of country regarded as a statical phenomenon, without reference to either its internal anatomy, its physiology, or the mode and causes of its development; it asked for no reason. The new method seeks dynamical interpretations of all geographical phenomena, and asks how, and why, things are as they are.

A range of hills is no longer simply an elevated tract of country, delineated upon a map by certain contour lines, but it becomes the expression of facts of structure produced in a particular way, out of materials of a particular kind, by agencies the nature of which can often be inferred directly from the data supplied by the topographic map itself. In like manner, the history of a river-system, the development and interactions of its parts, and the climatic vicissitudes that have affected its drainage basin can be deduced from the map by the familiar exegetical device of reading the spirit of the commentator into the text. The department of geographical study, seeking among other objects the cultivation of this faculty, though deriving much of its initial impulse from the suggestion of British workers, from Hutton and Playfair to Ramsay, Jukes, Geikie, Jukes-Browne, and Marr, has been organised and placed upon a systematic basis, principally by the labours of workers like Penck and Bruckner on the Continent, and the host of American geomorphologists, foremost amongst whom must be placed Davis, Salisbury, and Shaler.

---

[1] "The Interpretation of Topographic Maps." By R. D. Salisbury and W. W. Attwood. Pp. 84+cxx plates. Department of the Interior, U.S. Geological Survey, Professional Paper, 60. (Washington: Government Printing Office, 1909.)

In the magnificently illustrated volume before us, Prof. Salisbury and Mr. Attwood have attempted to show how a topographic map may be made to yield up all its secrets. The first section of the preliminary letterpress is substantially that which appears in the explanation of each fasciculus or folio of the geologic map of the United States. It sets forth the nature of the features delineated in the three categories of (1) water (blue), (2) relief (brown), and (3) culture (black). The last term might easily be misunderstood by a British reader—it does not refer to cultivation only, but to all the signs of man's handiwork, such as roads, railways, buildings, boundaries, that appear upon the maps. The geological details are, of course, expressed by the conventional signs and colours adopted by the national service.

The succeeding sections deal with elementary concepts of relief, followed by a succinct discussion of the various agents of change and their effects, under the headings wind, stream-erosion, alluviation; topographic forms resulting from unequal hardness of rocks, erosion cycles, stream piracy and adjustment, topographic effects of ground-water, glaciation, coastlines, volcanism, faults, special types of lakes. Each of these subjects is illustrated by one or more maps, mostly on the scale of about one inch to the mile (1/62,500 instead of 1/63,360), of actual pieces of country, and in most cases by pictorial illustrations.

The maps are beyond all praise for the beauty of their execution and the admirable printing; indeed, the contrast between the splendid series of maps of which these are specimens selected merely because they portray typical features of topography, and our British maps, inferior in delicacy, heterogeneous in style, badly printed on poor paper, is very humiliating to our national pride. The contour lines are beautifully engraved, and are drawn at intervals of 20 feet, whereas the 1-inch maps of the British Isles, with the exception of a portion of a single sheet, that embracing Longridge Fell in Lancashire, have contour-intervals of 100 feet, and even our 6-inch maps are contoured only at the same intervals, saving those of the fortunate counties of Lancashire and Yorkshire, the surveys of which had been accomplished prior to 1858, when the depreciation of our maps was decreed.

A Tidal Lagoon formed by sand spit at the mouth of San Luis Obispo Creek, California.

If any adverse criticism were offered of this admirable manual it would be that the landscape illustrations do not in all cases represent the area or even the district shown upon the map, though illustrating similar phenomena, or, where the area is the same, the point of view cannot be identified. These are small defects in a work that cannot fail to be of the utmost value to students and teachers the world over, and particularly to those of America, for whom it is designed, and those of Britain, who may have a century or two to wait for the materials out of which a similar memoir could be prepared for our own country.

P. F. K.

THE OXFORD UNIVERSITY MUSEUM.[1]

FEW [illegible] [illegible] to the pursuit of science [illegible] more interesting history or a more distinct individuality than the Oxford University Museum. It is the resultant of many of the most characteristic activities, and embodies some of the most earnest aspirations of the latter half of the nineteenth century. The two chief lines of scientific and artistic effort which converged upon Benjamin Woodward's Gothic pile found their most typical exponents in Acland and Ruskin; each of them a genuine enthusiast, each with not a few of the faults of his qualities, and each destined to witness the realisation of some of his ideals and the failure of others in the fabric which forms an appropriate monument of their lifelong association.

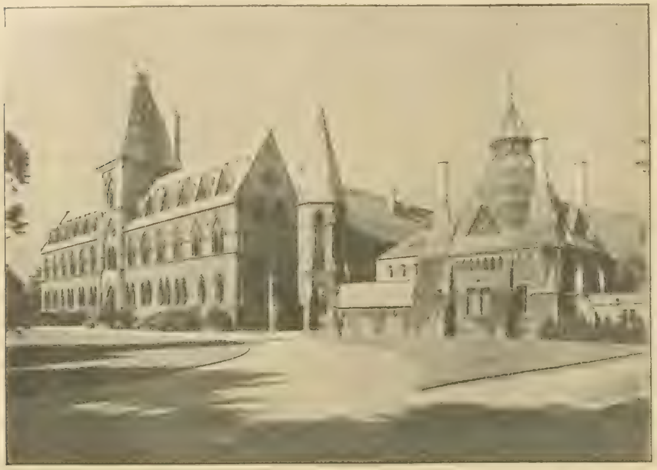

FIG. 1.—The Oxford Museum from the south-west. From "A History of the Oxford Museum."

The newer buildings which at the present day are grouping themselves around the central structure of the museum constitute with it an apt symbol of the manner in which the university has responded to the needs of scientific research and education in modern times. Oxford can never forget that she inherits a great tradition—literary and artistic, as well as philosophical. When first aroused to a sense of her responsibility in view of modern scientific demands, her main endeavour was to graft the new upon the old. No visitor to the original part of the museum can fail to recognise the outcome of this spirit in the structure itself, which is Gothic both in conception and in detail, in the blend of the conventional and the realistic in its scheme of decoration, and in the array of statues which, forming an integral part of the design, carry the mind of the observer from Hunter and Harvey back through the ages to Hippocrates and Aristotle. But the outlook of the University is to the future as well as to the past, and in the various annexes which have sprung up around the original building we see evidence of a desire to "let the dead bury their dead," and to enter frankly upon the task of meeting modern requirements with a single eye to practical efficiency. Still, whatever scientific developments may yet be in store, the Museum Court will, we may hope, always remain to testify to the fact that the future will be none the worse for having some of its roots in the past. It must be confessed that the organisation of scientific study in the university has hardly kept pace with the growth of scientific appliances. There is still too much clinging to respectable but antiquated methods in the system of college tuition, and, above all, in that of examinations. A promising field of university reform lies open in this direction.

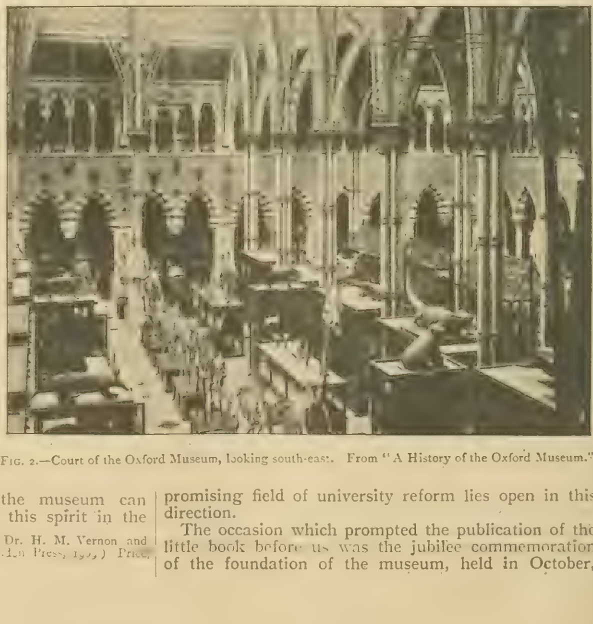

FIG. 2.—Court of the Oxford Museum, looking south-east. From "A History of the Oxford Museum."

The occasion which prompted the publication of the little book before us was the jubilee commemoration of the foundation of the museum, held in October,

---

[1] "A History of the Oxford Museum." By Dr. H. M. Vernon and K. [illegible] Vernon. Pp. [illegible]. (Oxford, Clarendon Press, [illegible].) Price, 1s. [illegible].

1908. Dr. and Mrs. Vernon have succeeded in presenting an admirable account of the progress of science in Oxford from the days when Willis, Bathurst, Seth Ward, and Robert Boyle held their meetings at the lodging of Wilkins, Warden of Wadham, in which college Sydenham and Wren were at that time undergraduates. The history of the struggles and ultimate success of the little band who, led by Acland, Daubeny, and Walker, with help from Pusey, resolved that, so far as in them lay, science should take its proper place among the activities of Oxford, is carefully and sympathetically recorded. The work of the museum during the fifty years of its existence—work associated with the names of Phillips, Brodie, Prestwich, Rolleston, Moseley, Lankester, and Burdon-Sanderson, to mention only a few—forms the subject of a specially interesting chapter; and the book ends with an account of the jubilee commemoration itself. We wish that the authors had found space to include in their record the address delivered on that occasion by Dr. Vernon Harcourt—an address justly characterised by them as "most instructive and entertaining." Extracts, however, are incorporated in the body of the work.

The book is attractively got up, and illustrated with some good photographic plates, in the legends of two of which, unfortunately, the points of the compass are incorrectly given. We reproduce views of the exterior and part of the interior of the original building.

F. A. D.

THE DISTRIBUTION OF FRESH-WATER EELS.[1]

It is certain that the hydrographers of the *Challenger* and other deep-sea expeditions made their physical observations in the Atlantic Ocean depths all unsuspecting of the fact that thereby they were essentially helping to make an important contribution to the natural history of the fresh-water eel. Yet this fact constitutes part of the interesting information derived from a perusal of Dr. Schmidt's latest publication, a continuation of his previous famous researches upon the eel which have previously been described in the pages of NATURE.

In spite of the abundance and wide distribution of the genus Anguilla, the first and final chapters of its life-history were, until quite recently, matters of profound obscurity. It is a fact of common observation and knowledge that the elvers or glass-eels which in the spring months ascend our rivers frequently in countless numbers develop into young eels, and also that adult eels in their silvery breeding dress descend to salt water in autumn; but there, until a few years ago, knowledge ended and conjecture began. It was a common belief in this country that estuaries and harbours probably afforded the spawning places. In 1893 the Italian zoologists Grassi and Calandruccio proved that *Leptocephalus brevirostris,* a deep-water fish of obscure systematic position taken in the Mediterranean, was really a larval stage of the common eel. Dr. Schmidt and his Danish colleagues, whose energies were first directed upon this particular research because of the economic importance of the eel-fishery in their country, traced the early "elver" stage down to the open sea, and at last, by their deep-water investigations in 1904–5, succeeded in locating an important breeding region off the west coasts of the British Isles at depths of more than 1000 metres. Subsequent trawlings have revealed the distribution of the early (Leptocephalus) larval stage in the Atlantic Ocean from the Færoë Islands to Gibraltar, but always in water of more than 1000 metres depth and not less than 7° temperature. From these investigations, Dr. Schmidt came to the conclusion that "in order to propagate, this species demands certain external conditions (chiefly great depths with high temperature and salinity of water)," and it was to test the validity of this conclusion for other parts of the world that the research upon the geographical distribution of the fresh-water eel was commenced.

The Anguilla genus is widely distributed, being found in the Atlantic as well as in the Indian and Pacific regions. However, the main point of this inquiry will be best indicated by limiting our consideration to the regions of America, Europe and Africa where most data are available, and where (if we except eastern Africa) the question is simplified by being confined to two species only, viz. *Anguilla vulgaris,* the European species, and *A. chrysypa,* the American form. Now fresh-water eels are entirely lacking on the Pacific shores of North and South America (and of course in the river systems which have their outlet on this coast). On the Atlantic side, however, they are abundantly represented in the easternmost parts of Canada and the United States, and are found from southernmost Greenland and Labrador to the West Indian Archipelago and Guiana. On the other hand, they are lacking in South America south of Guiana, no single record, for example, occurring of the presence of fresh-water eels in the large river systems of Brazil and Argentina. They are found on practically all the islands of the Atlantic north of the Equator (Bermudas, Azores, Madeira, Canaries, Iceland, &c.), and, what is especially worthy of attention, they occur on islands where other fresh-water fishes are completely lacking. On the eastern side of the Atlantic they are found from the region of North Cape and southwards along all the coast of Europe, on all coasts of the Mediterranean, and on the north-western part of the coast of Africa. In Senegal they disappear, and are absent from all the rest of the west coast of Africa as far as Cape Colony, where the Indian Ocean species begin to be met with.

Thus in tropical, temperate, and even Arctic regions, Atlantic fresh-water eels are found—truly a wide-spread habitat, and one affording extremely varied environments! But it is on account of "this astonishing power to submit to most varied outer conditions" that their absence from certain regions is apparently incomprehensible. Why, for example, have they not been able to penetrate further southwards along the coasts of the Atlantic? In order to understand this, it is necessary to recall some of the results of later years' marine biological investigations, especially "the ascertained fact that very often the sensitiveness of a species of fish to its surroundings differs a great deal in its growth-period and in its spawning-time, so that during the latter its requirements as regards the outer conditions (depth, temperature, salinity) are much more definite and very different from those during the first, the effect of which is that the distribution during spawning-time may often be very different from that during growth. . . . It is in the first instance the requirements as regards the outer conditions during spawning time which influence the distribution."

The earlier investigations upon the spawning places of the eel have shown that in order to be able to propagate, the European fresh-water eel requires great depth (at least 1000 metres), a high salinity (more than 35·2 per cent.) and temperature (more than 7° C.) at this depth; and this is where the importance of the hydrographical data obtained from the temperature curves of the *Challenger, Valdivia,* and other deep-sea expeditions comes in. It is shown that "the absence of eels in all the large fresh-water systems of South America, western North America, and West Africa is due to the fact that the temperature in the deeper layers of the adjacent seas is too low to admit of the propagation." Incidentally, an explanation is afforded of the hitherto puzzling lack of success which attended the transplantation of eels from the eastern to the Pacific States by the U.S.A. Fish Commission in 1874 and other years. The eels themselves flourished in their new surroundings, but the Pacific Ocean afforded no place for successful reproduction.

---

[1] On the Distribution of the Fresh-water Eels (Anguilla) throughout the World. (1) Atlantic Ocean and Adjacent Regions. A Biogeographical Investigation. By Johs Schmidt. With one chart. Pp. 45. (Copenhagen, 1909.)

Oceanic hydrography has thus supplied the indispensable key to the elucidation of a point in the biology of a species which is universally regarded as a fresh-water form. More strictly, however, *Anguilla vulgaris* may be considered as an oceanic species which has acquired the habit of migrating to fresh water for food and protection.

After all, the most interesting feature of this work is that it deals with an extreme case of the problem of the relationship between physical environment and fish propagation, a most important question in connection with the economic aspect of the fish supply. Dr. Schmidt has contributed pioneer work of great value towards the understanding of these phenomena in regard to other species besides the eel. We may mention, for example, his research upon the plaice and cod in Icelandic waters, where he has shown by marking experiments that a regular spawning migration takes place into the warmer Atlantic water off the south and south-west of the island. Here again the phenomena are clear and comprehensible, because they are, as it were, "writ large"—the difference in temperature between the cold water off the north and east and the warmer Atlantic waters off the south and west of the island being very marked, which renders the migration practically an absolute necessity for the survival of the offspring. Essentially the same in principle are the problems of correlated physics and biology in British seas which still, to a great extent, await elucidation. But here the phenomena are not "writ large"; on the other hand, they can only be demonstrated by the study of observations made with fine precision and extended over a considerable period of time. A. E. H.

THE PARIS FLOODS.

IT is now an evident fact that Paris has recently suffered the ravages of an inundation greater and more severe than any which have visited the city within the last two and a half centuries. A gauge at the bridge of La Tournelle shows the surface of the water as having reached a height above the bed of the river of 27 feet 10½ inches. Normally, it is only about 8 or 9 feet, and it is necessary to go back so far as the year 1658 in order to find any record exceeding, or even approaching, this figure. At that date the height attained was 28 feet 10½ inches. A few years previously (1651) there was a flood of 25 feet 8 inches, and in 1649 another of 25 feet 2 inches. The flood of 1802, great as it was, did not exceed 24 feet 5 inches, and that of 1876 only reached 21 feet 11 inches.

The known records are as follows:—

		ft.	in.
February	1649	25	1½
January	1651	25	8
February	1658	28	10½
February	1690	24	9
March	1711	25	0
December	1740	25	11
February	1764	24	0½
January	1802	24	5
March	1807	22	0
January	1910	27	10½

The causes of the flood are not quite so obvious as the effects. At first sight it would appear that there is no very satisfactory explanation to be vouchsafed. In the watershed of the Seine and its tributaries there is an absence of lofty ranges with snow-capped summits, capable of producing copious liquidations such as prevail in mountainous regions. But on the other hand, there are numerous impermeable districts within the Seine Basin where the rainfall finds its way almost entirely into the river bed, and if to the effect of a prolonged precipitation in these areas there be added the far from negligible contribution of melted snow from the impermeable Morvan Plateaux, produced under the influence of a sudden and abnormal rise in temperature, we need not pursue inquiries very much further in order to arrive at an adequate solution of the problem.

The Seine at Paris is formed by the confluence of three important streams: the Yonne, the Upper Seine, and the Marne. Of these the Yonne is the only one presenting torrential characteristics; it rises rapidly, and subsides as quickly. The other two streams move more slowly, and change less abruptly. After a period of heavy rainfall the flood waters of the Yonne arrive first at the point of confluence, reaching it at the end of three or four days, and they produce the greater portion of the rise in level. Four or five days later the waters of the Upper Seine and Marne arrive, having been fed by filtrations through more permeable ground and by surfeited springs, and these simply serve to maintain the effect of the previous increment. If towards the end of this period the previous meteorological phenomena in the upper reaches repeat themselves, the effect produced is that of a single continuous flood of considerable intensity.

Fortunately, floods in the neighbourhood of Paris can be predicted sufficiently in advance to enable remedial, or at any rate palliative, measures to be undertaken. The Seine, as has been pointed out, rises but slowly, and the effects of floods in its affluents are visible several days beforehand, and can be announced accordingly. There is ample warning for the inhabitants to withdraw, if need be, from the threatened quarters. An empirical rule has even been established which enables the height attainable by the flood to be approximately stated. The rise of the Seine at Paris is just about double the mean of the partial rises in its affluents at certain fixed points. The hygrometric service of Paris, therefore, plays a very useful part in issuing these forecasts, and renders valuable service to the community at large.

PROF. F. PURSER.

THE news of the death of Prof. F. Purser, professor of natural philosophy in the University of Dublin, announced in last week's NATURE, has been received with deep regret. His life had just reached the regular period of seventy years, and intellectually he was as vigorous as ever.

Prof. Purser was one of the ablest and most brilliant members of a very clever family. His father managed Guinness's Brewery in the time of Sir Benjamin Guinness, and it was to a great extent owing to his skill, foresight, and enterprise that the brewery attained the colossal dimensions it possesses at present. His elder brother was a mathematician of a very high class, and was for several years professor in Queen's College, Belfast.

Two of his cousins were distinguished professors of the University of Dublin. One held the chair of institutes of medicine, or physiology; the other, Dr. Louis Purser, was professor of Latin, and is still public orator.

Prof. Purser's university career was very brilliant. He obtained a science scholarship in 1859, a large gold medal in mathematics, pure and applied, at the moderatorship examination in 1860; Bishop Law's mathematical prize, the MacCullagh prize, and in 1872 fellowship. At that time the fellows of Trinity College, Dublin, were supposed to be members of what had recently been the Established Church, and on their election were obliged to make a declaration which was partly of a religious character. Frederick Purser was a Moravian, and though no question would have been asked as to his special form of belief, he considered that he could not with truth make the required declaration, and consequently the fellowship he had won was declared vacant.

In 1873 Fawcett's Act abolished religious tests in the University of Dublin, and Purser began to read again for fellowship, which he gained for the second time in 1879. This has always been regarded as a wonderful feat by those who are best acquainted with the nature and difficulty of the fellowship examination in Trinity College. In 1902 Purser succeeded Tarleton as professor of natural philosophy, which professorship he held until his death. In 1905 and 1906 he was a vice-president of the Royal Irish Academy. He published in the Proceedings of the Academy some fine papers on the applications of Bessel's function to various difficult questions in physics. Some beautiful investigations of Prof. Purser are to be found in Tarleton's "Introduction to the Mathematical Theory of Attraction." Purser's publications, however, represent most inadequately the extent of his knowledge and his genius.

A more profound or accurate thinker than Prof. Purser it would be difficult to find. He was not merely a mathematician—he was also a metaphysician of the highest order. His paper, published many years ago in *Hermathena*, on "Hamilton's System of Natural Realism," was a work of rare ability. In that paper he showed that Hamilton's theory, when stripped of its absurdities and inconsistencies, was almost the same as the theory of Kant. As a metaphysician Prof. Purser was in the main a follower of Kant. Of geometrics of space of more than three dimensions he had a poor opinion, and looked upon them as little more than algebraical exercises.

Possessed of considerable wealth, he expended it with the greatest generosity. He was a munificent benefactor of Queen's College, Belfast, where his brother was a professor; of Trinity College, Dublin; and of the Royal Irish Academy.

Prof. Purser's chief fault—if it may be described as such—was one which appears to belong to the whole Purser family, that is, the fault of thinking far too little of his own powers and of the value of his own performances.

NOTES.

For the meeting of the British Association for the Advancement of Science, which is to take place this year at Sheffield on August 31 and following days, under the presidency of Prof. T. G. Bonney, F.R.S., the following presidents have been appointed to the various sections:—A (Mathematical and Physical Science), Dr. E. W. Hobson, F.R.S.; B (Chemistry), Mr. J. E. Stead, F.R.S.; C (Geology), Prof. A. P. Coleman; D (Zoology), Prof. G. C. Bourne; E (Geography), Dr. A. J. Herbertson; F (Economic Science and Statistics), Sir H. Llewellyn Smith, K.C.B.; G (Engineering), Prof. W. E. Dalby; H (Anthropology), Mr. W. Crooke; I (Physiology), Prof. A. B. Macallum, F.R.S.; K (Botany), Prof. J. W. H. Trail, F.R.S.; L (Educational Science), Principal H. A. Miers, F.R.S.

In a speech delivered at Washington last week, Commander Robert E. Peary proposed, on behalf of the Peary Arctic Club, that the National Geographic Society should unite with the club in the organisation of a United States South Polar Expedition, to start in the autumn of this year. He promised that the Peary Club would lend the *Roosevelt* for the purposes of the expedition, but stated that he himself would be unable to assume the command in person. The proposal has since been accepted by the directors of the National Geographic Society. All proposals which aim at the extension of knowledge of the Antarctic area are to be welcomed, but now that so many projects for the exploration of the south polar regions are to the fore, it is necessary to consider how Commander Peary's scheme stands in relation to other Antarctic enterprises. The only expedition at present in the field is that under Dr. Jean Charcot on board the *Pourquoi Pas*, which a year ago penetrated the Antarctic regions to the south of South America. It intended to make its way westwards, and, if possible, undertake a "dash" to the South Pole from the ship's winter quarters. If the expedition makes its way northwards again this season, news of it should be received in the course of the next two months. The British expedition now in course of organisation by Captain Scott will make its headquarters in McMurdo Sound, and, if possible, land a small party on King Edward VII. Land. The expedition proposed by Commander Peary will not interfere with these plans in any way, since it is suggested that its base should be on the opposite side of the Antarctic continent, that is to say, on Coats Land, in the Weddell Sea, south of the Atlantic Ocean. This is the coast which Dr. W. S. Bruce, its discoverer, wishes to make the base of a Scottish Antarctic expedition, and Sir Ernest Shackleton has also stated that if he should go south again he would probably attempt to reach the Pole from the side of the Weddell Sea. An alternative base suggested by Sir Ernest Shackleton is Gaussberg, to the south of the Indian Ocean, off which the German expedition under Dr. Von Drygalski wintered in 1902. Gaussberg is situated on the Antarctic circle; the most southerly known point of Coats Land is just beyond the seventy-fourth parallel, or 960 geographical miles from the Pole, while Cape Royds, in McMurdo Sound, where Captain Scott proposes to winter, is in between 77° and 78° south latitude, nearly 750 geographical miles from the Pole.

Mr. W. Bateson, F.R.S., and Dr. H. T. Bovey, F.R.S., have been elected members of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services."

The Julius Thomsen memorial lecture of the Chemical Society will be delivered on February 17 by Sir Edward Thorpe, C.B., F.R.S.

Four lectures on "The Anatomy and Relationships of the Negro and Negroid Races" will be delivered in the theatre of the Royal College of Surgeons, Lincoln's Inn Fields, by Prof. Arthur Keith (conservator of the museum), on February 14, 16, 18, and 21. Ladies and gentlemen will be admitted to the lectures on presenting their private visiting cards.

The annual conversazione of the Selborne Society will be held on Friday, February 18. An address will be given by Sir John Cockburn, K.C.M.G., and a lecture on "Selborne and its Associations with Gilbert White" by Mr. E. J. Bedford. There will be a large display of exhibits under the microscope, as well as exhibits of natural-history specimens, nature photographs, and other objects of scientific interest.

Sir Patrick Manson has been elected a correspondant of the Paris Academy of Sciences in succession to the late Sir Burdon Sanderson.

According to a Reuter telegram from Berlin, published in the *Times* of February 3, the expedition dispatched to German East Africa to collect dinosaurian remains is proving successful. A femur, measuring 6 feet 10 inches, is specially mentioned, on account of being nearly 2 feet longer than the corresponding bone of the Carnegie Diplodocus.

The King has presented to the natural history branch of the British Museum the skeleton of his famous thoroughbred "Persimmon," which has been set up by Rowland Ward, Ltd., Piccadilly. This is the first complete skeleton of a thoroughbred to be exhibited in the museum, the skeleton of "Stockwell," which is also contained in the collection, being represented in the exhibited series merely by the skull and the limbs of one side. In common with most or all thoroughbreds with the blood of "King Tom" in their veins, "Persimmon" exhibits a trace of the sinuous skull-profile characteristic of Arabs. The museum previously possessed a statuette of "Persimmon," presented in 1905 by H.R.H. the Prince of Wales.

The first ordinary meeting of a new society, formed by the amalgamation of the Society of Engineers and the Civil and Mechanical Engineers' Society, was held on Monday, February 7, at Caxton Hall, Westminster. Mr. Diogo A. Symons, the first president of the new Society of Engineers, delivered an inaugural address. Referring to the examination which is to be the qualification for fellowship of the society, he believes that its introduction will have the same beneficial effect as has been the case in the Institution of Civil Engineers. Proceeding to more general subjects, he directed attention to the value of workshop training to engineering students, whether they intend to take up the civil or the mechanical branch of the profession. Speaking of the education of young engineers, Mr. Symons emphasised the importance of a thorough grounding in fundamental principles before any attempt at specialisation is attempted, and laid stress on the advantage of gaining engineering experience with a contractor on public works. The tendency of engineering students to accept salaried appointments after too brief a training was deprecated, because such appointments usually involve loss of valuable instruction and experience.

According to the *Pioneer Mail* of Allahabad, a preliminary astronomical conference was held recently at Papanasanum, and another will be held later at Kaladi (Travancore Native State). Astronomers from all parts of India, representing the three different schools of astronomy, viz. Siddhanatha, Vakya, and Drigganitha, are being invited. It is also proposed to give a prize of not less than Rs. 100 (one hundred) to each of these different schools of astronomy; but if Pundits from distant parts cannot come to the conference, they may send written papers in Sanskrit or English. The objects of the conferences are to check the irregularities in calculations now found in the Indian Almanac, and to arrive at some satisfactory solution with reference to the system of calculation to be adopted in the making of future almanacs.

The second Congrès International du Froid will be held at Vienna on October 6–12, before the close of the International Sporting Exhibition, and the University has been lent for the meetings. Briefly, the subjects to be discussed are the science of cold; the industrial production of cold; the application of cold to alimentation and to other industries; transport; and legislation. The Archduke Leopold Salvator, at the request of the Emperor of Austria, is acting as patron of the congress, and receptions will be given to the delegates by the Court and by the towns of Vienna, Budapest, &c. Papers must be submitted to the Association International du Froid through the British committee. Full particulars of the congress may be obtained from Mr. R. M. Leonard, honorary secretary for the United Kingdom, 3 Oxford Court, Cannon Street, London, E.C.

The scientific expedition dispatched to Dutch New Guinea by the members of the British Ornithologists' Union has sustained a great loss by the death of Mr. Wilfred Stalker, one of its most skilled naturalists. At the present time no details are known beyond the melancholy fact that he was drowned on January 9. The news was received by telegram from Batavia on February 1, and had probably been forwarded by steamer from the Aru Islands. With this telegram Mr. Ogilvie-Grant received a long letter from Mr. Stalker, written from "Amboina, December 24, 1909." In this he stated that he had been successful in engaging the services of 150 carriers, and was expecting the arrival of Mr. Walter Goodfellow, the leader of the expedition, in a few days. He also mentioned the dispatch of various cases containing collections of mammals and birds, &c., which had been procured in Central Ceram, and are likely to prove of great interest. Mr. Stalker left England about a year ago, and proceeded to the Aru Islands to obtain living examples of birds of paradise for Sir William Ingram. It had been arranged that, after completing this engagement, he should join the other members of the British Ornithologists' Union expedition, filling up his time until their arrival by collecting natural-history specimens and in making the preliminary arrangements for transport in New Guinea. His letter, mentioned above, states how usefully he had employed his time in carrying out his instructions. Mr. Stalker had already had considerable experience of life in New Guinea, having spent several years (between 1904–6) at the gold mines on the Mambare River, in the northern part of the British territory. It was then that he first began to collect specimens for the Natural History Museum. Subsequently, at the suggestion of Mr. Oldfield Thomas, who had discovered his great ability in trapping and preparing mammals, he was sent by Sir William Ingram and the Hon. John Forest to Alexandra, in the northern territory of South Australia, and in 1907 to Inkerman, in East Queensland. In both these places he did admirable work, and formed fine collections of mammals, which were presented by his patrons to the Natural History Museum. In 1909, in company with Mr. C. R. Horsburgh, he again visited British New Guinea and the Aru Islands on behalf of Sir William Ingram, and was successful in bringing back a large number of living birds of paradise, including a male of the beautiful blue bird of paradise (*Paradisornis rudolphi*), which had not previously been brought to Europe alive. Early in 1909, after a short stay in England, he again started on the present undertaking, when he so unfortunately lost his life. Mr. Stalker was quite a young man—only thirty-one years of age—having been born on January 17, 1879, and it is sad to think that the successful career of this talented naturalist should have been terminated so early and in so tragic a manner.

Dr. C. C. Hoffeus, of Shöneberg, near Berlin, has favoured us with a copy of the *Leipziger Tageblatt* for

July 24, 1909, in which he recommends the alliaceous plant locally known as "knoblauch" (*Allium ursinum* and also *A. acutangulum*) as a table-vegetable. These plants grow abundantly at Rosenthal, where cabbages cannot easily be raised, and, when properly cooked, are stated to have a flavour superior to that of spinach, the garlicky odour entirely disappearing after a prolonged soaking in water and the application of salt.

THE Transactions and Proceedings of the Perthshire Society of Natural Science for 1908–9, vol. v., part i., contain the report of an address delivered in March last by the president, Mr. W. Barclay, on the proposal to re-afforest large areas in Scotland. The scheme is cordially approved in the address, and a resolution was carried at the meeting in support of the recommendation of the Royal Commission that a State forestry department should be established, with power to put the work in hand. The scheme, it was urged, would eventually prove a financial success, and would provide present employment.

No. 2 of section *b* of vol. xxviii. of the Proceedings of the Royal Irish Academy is devoted to a list of the Neuroptera of Ireland, by Messrs. J. J. F. X. King and J. N. Halbert. This catalogue, which is to replace one published more than twenty years ago by one of the present authors, it is hoped will form a standard of reference for future observations. Although our knowledge of the native dragon-flies, like that of the other Neuroptera, is far from complete, there is no doubt that Ireland possesses fewer of these insects than Great Britain. Twenty-five species were included in the Irish list of 1889, but the number must now be reduced to twenty-three. The study of the may-flies has been so neglected that there are few changes to record from the old list.

ANGLER-FISHES (Pediculati) and their habits form the subject of a richly illustrated paper by Dr. T. Gill, published in the Smithsonian Report for 1908. Nearly all the species inhabiting shallow or moderately deep water are provided with an angling apparatus—the "illicium"—which undoubtedly serves as a rod, line, and bait, although the action is probably automatic. Certain stoutly built members of the group are, however, denizens of deep water, and in these the fishing apparatus has been modified into a rod with a bulb furnished with a phosphorescent terminal portion, while the surrounding "bait" has likewise been specialised and augmented; and, in addition to all this, a lantern and worm-like lures are present. How efficient this apparatus must be will be apparent to all who have witnessed salmon-spearing by torchlight.

GREAT interest attaches to an article by Dr. R. S. Lull, in the January number of the *American Journal of Science*, on the distribution of dinosaurian reptiles. It should be premised that dinosaurian remains are unknown from Central and North-eastern Asia, which may be attributable either to our lack of knowledge of the palæontology of that area or to the circumstance that these reptiles never occurred there. The theropod group is believed to have originated in North America—"Laurentia"—whence they migrated in one direction, probably at a late epoch, into South America, and in another, by way of Greenland and Iceland, to Europe, and thence to India, Africa, Madagascar, and Australia. The Sauropoda, on the other hand, are regarded as an Old World group, migrating early in the Jurassic into the great southern continent of the Old World, "Gondwanaland," and also into the New World. In the southern hemisphere they had a distribution nearly as extensive as that of their carnivorous cousins, and survived long after they had disappeared from the north, occurring in India during some part of the Cretaceous, and in Patagonia—their last stronghold—during the Laramie, or topmost Cretaceous. On account of their semi-aquatic habits, they were independent of complete land-connections, and could thus extend their migrations across areas impassable to the strictly terrestrial Ornithopoda (Orthopoda), as typified by the iguanodon. This may be the reason why the latter group never succeeded, so far as our present information goes, in penetrating the southern hemisphere, although it is possible that the date of their radiation may have been later, when communication between Europe and Gondwanaland was interrupted; while it has also to be borne in mind that, judging from their dentition, they were dependent upon a particular kind of food. Originally the Ornithopoda were probably a North American group, and the horned, or ceratopsian, section appears to have been restricted to the western continent.

THE seventh volume of the *Journal of Experimental Zoology*, which was completed with the November (1909) number, contains no fewer than a dozen memoirs on regeneration in animals. Now that the study of this subject includes the effect of drugs upon the rate of regeneration, with the whole pharmacopœia on the one hand and the entire animal kingdom on the other from which to select material for experiment, there seems no reason why such researches should ever come to an end. Of course, the same may be said of almost any other branch of biological investigation, and, indeed, the rapid accumulation of literature at the present time threatens either to swamp biologists altogether or else to force them to take refuge in a very narrow specialisation.

THE problem of sex-determination continues to receive a very large share of attention from cytologists. One of the most notable recent contributions to the already extensive literature of the subject is a memoir, by Prof. T. H. Morgan, entitled "A Biological and Cytological Study of Sex Determination in Phylloxerans and Aphids," published in the *Journal of Experimental Zoology* for September, 1909 (vol. vii., No. 2). In addition to the author's own observations, this paper contains a critical review of the recent literature of the subject. The theory of accessory chromosomes and the Mendelian interpretation of sex are dealt with. It is admitted, however, that the problem has as yet by no means reached a satisfactory solution. Prof. Morgan regards the quantitative interpretation of sex-determination as only the first rough approximation to such a solution, and he thinks that the accessory chromosome may follow sex or be associated with other differences that determine sex rather than be its sole cause.

THE genus Œnothera has received world-wide attention from botanists since Prof. de Vries founded his mutation theory largely on the variations he obtained by cultivation of certain wild forms. In the hope that North American and European botanists may be induced to make a careful examination of other wild colonies, Mr. R. R. Gates, who has already investigated several of the variants, has compiled an analytical key to the principal segregates and mutants of the genus, which is published in the twentieth annual report of the Missouri Botanical Garden. Ten species and fourteen forms derived from *Œnothera Lamarckiana* are delimited.

THE consequences of cattle-grazing in Indian forests are discussed by Mr. J. W. Best in the *Indian Forester* (November, 1909), where he notes the results of his observations in a division of the Central Provinces. Grazing is restricted to definite areas where least harm can be done, and, as a rule, goats are prohibited entirely from reserved forests. The destruction of young trees is, of course, the chief danger, since it leads to uneven regeneration. A noticeable feature is the increased development of certain trees with protective devices, such as armed species of Gardenia and the thorny *Zizyphus Oenoplia*. The saplings of *Butea frondosa* also escape the ravages of the cattle; and since this tree is valuable for the cultivation of lac insects, it is recommended that it should be extensively grown on grazed areas.

SEVERAL facts of importance in connection with the development of monocotyledonous embryos are recorded by Mr. W. E. Evans in an account of the germination of Asparagus, Ruscus, and Polygonatum appearing in Notes from the Royal Botanic Garden, Edinburgh (August, 1909). In the case of Asparagus, the axis of the seedling soon breaks through the cotyledon sheath, although the first two internodes do not elongate, so that one or two small hypogeous scale leaves are found at the base. The buds in the axils of these leaves give rise to the first beginnings of the sympodial rhizome. The primary root thickens, and presents the appearance of a pull-root. The germination of Ruscus and Polygonatum seedlings is similar, but several basal scale leaves are formed, and in Polygonatum the hypocotyl takes part in the formation of the fleshy rhizome.

ON the island of St. Vincent cotton and arrowroot provide the most valuable agricultural export commodities, while cacao and sugar are of subsidiary but appreciable importance. The report for 1908–9 of the botanic station, published with the reports of other agricultural establishments, presents several interesting facts concerning these economic products. The Sea Island cotton, by reason of favourable soil and climate in the coastal districts where it is grown, has maintained its reputation as the best quality produced in the West Indies, and the quantity exported during the year has increased in amount; but lower prices and bad weather have caused a small decrease in the area planted and in the output. Arrowroot can be grown in all parts of the island, and the supply could be increased if fresh markets were obtainable. A feature of the cacao cultivation is the necessity for shade, for which purpose the leguminous tree *Gliricidia maculata* is utilised.

THE Department of Lands, New Zealand, has sent us a copy of the surveyor-general's report for the year 1908–9. The greater part of the report is occupied with an account of the progress of the different surveys, but some of the notes and appendices are of general interest. The Milne seismograph at Christchurch registered forty-six earthquakes, the average annual number during the preceding six years being eighty-two. The record of the Messina earthquake will prove of considerable interest, as Christchurch is not far from the antipodes of Calabria. A foundation has been laid for the measurement of secular movements of the New Zealand coasts in the determination of the mean sea-level at Auckland, Wellington, and four other ports, and its reference to permanent bench-marks on the adjoining shores. The Wellington Harbour gauge-charts exhibit many instances of very pronounced seiche-oscillations, much more so than at the other ports, and it is found that in most cases they are accompanied by a change of wind from north to south or *vice versâ*, the wind at the time being generally strong.

THE University of California has issued, as the fourth part of vol. vii. of its Proceedings, a report on the shell-mounds of the San Francisco Bay region, by Mr. N. C. Nelson. The environment of these shores favoured occupation by numerous fishing tribes, and no fewer than 425 mounds, some of considerable extent, have been mapped and described. The culture disclosed in these mounds is generally uniform and of the Neolithic type, rude stone implements being found only in inconsiderable numbers. These people buried their dead in the collections of shells and other débris in the neighbourhood of their dwellings, and a large collection of osteological remains has been made which still awaits examination. It seems probable that the builders of these mounds were of the same race as the present Indians of the neighbourhood, but it is at present impossible to fix the approximate date at which they may have been formed. They are certainly of considerable age, because some species of oysters and mussels the shells of which have been recognised in the mounds have disappeared from the locality. From calculations of the daily supply of fish required by the group of families occupying a single site, Mr. Nelson estimates that the accumulation of shells in one mound may have extended over 3500 years.

THE Bureau of Science of the Government of the Philippine Islands has published parts iv. and v. of vol. iv. of its Bulletin, dealing respectively with medical sciences and general science in respect to the Philippine Islands. The former of these two parts, compiled with the assistance of the staff of the Philippine Medical School, presents a very complete medical survey of the town of Taytay, showing the diseases prevalent in the community and the conditions under which it lives. "While the conditions of the town are generally unsanitary, the death-rate varying in different years from 27·91 per 1000 to 45·42 per 1000, they at times become most unsanitary. Under the present conditions epidemic diseases such as cholera, typhoid, and bacillary dysentery are likely to occur from time to time." Various recommendations in regard to vaccination and water supply are urged to remedy this state of unhealthiness. The part which deals with general science contains papers on geology, road-making materials, and anthropology. The anthropological contributions contain a vast number of measurements which must ultimately prove of great value to the ethnologist, despite the accompanying absurd classification of the inhabitants into Iberian, Cromagnon, Australoid, Alpine, Adriatic species, varieties, &c.

A MEMORANDUM on recent weather and on the probable character of that of January and February, 1910, in the Punjab and north-west frontier-province of India, published by the Director-General of Observatories, concludes that the total precipitation in that locality will probably reach or exceed the average in the latter months. This inference is chiefly based on the fact that during fifteen out of eighteen years since 1890–1 an excess or a defect in the rainfall in December has been maintained in the two following months. In December, 1909, the area in question had an excess of 1·4 inches over the normal amount. The Director-General states that another favourable sign is that the vertical gradients of barometric pressure were abnormally steep during December.

IN the *U.S. Monthly Weather Review* for June last, just received, Prof. A. G. McAdie refers to the interesting and somewhat important problem of the prevention of damage by frost in orchards, &c. He states that the great mass of experiments made in California orchards shows that direct heating of the air by open fires has not been sufficient to prevent injury at times of very low temperature, and quotes a recent experiment of a careful observer there during a night when the temperature ranged between

19° and 24°. Very large amounts of wood and wet hay were burned, but, the air being dry and calm, the smoke rose straight upwards, and although three large fires were maintained between 20 and 30 feet of a certain tree, the temperature in the vicinity of the tree remained for some hours about 20°. Prof. McAdie's conclusion is that a proper cover spread some feet above the surface is the most effective means of protection of plants. When necessary, this may be supplemented by the use of small stoves, &c., placed on the ground.

A NEW form of watch-glass clip has been submitted for inspection by Messrs. J. J. Griffin and Son, Ltd., of Kingsway, London. It consists of two small metal rods joined by steel spring wire to form a holder, of lenticular section, which can slide over a pair of watch-glasses having their edges in contact. When desired, it can also be used for a single glass. The hold is very firm, and the clip is easily affixed and detached; it is also lighter, neater, and less cumbersome than the older brass contrivances. Within limits, the same clip will serve for different sizes of glass; but two sizes of clip are recommended for ordinary use, namely, those taking glasses up to 1¾ inches and up to 2¾ inches in diameter respectively.

THE December (1909) number of the Journal of the Institution of Electrical Engineers contains a paper read before the institution in May last by the president, Mr. W. M. Mordey, on some tests of the Mansbridge paper condensers described in these columns a year ago, and of the Moscicki glass condenser, or engineering form of the Leyden jar. Mr. Mordey finds that the losses on alternating current circuits only amount to about 0·6 per cent. in the case of the Mansbridge and 1 per cent. in that of the Moscicki condenser, the former being tested up to 500 and the latter up to 10,000 volts. In these circumstances the author points out that the general introduction of condensers on alternating circuits to compensate for the lag of current due to inductive loads becomes a possibility of the near future.

THE agenda paper of the general meeting of the Société française de Physique on January 21 contains, in addition to the business items and *résumés* of the papers read at the last meeting, a balance sheet for the session 1908–9. From it we gather that the society now has about 1500 members, almost equally divided between Paris, the rest of France, and foreign countries. The subscriptions for the year amount to 600*l.*, and the society has 10,000*l.* invested in French railways. The cost of printing the quarterly *Bulletin des Séances*, a volume of 300–400 pages per annum, and the fortnightly agenda and *résumé* of papers read, is about 140*l.*, and the cost of distribution of these publications to the members amounts to 130*l.* We offer the society our congratulations on its strong position and on the excellent work it is doing.

THE reconstruction of the Tyne North Pier, which has just been completed, forms the subject of illustrated articles in *Engineering* and in the *Engineer* for January 28. The importance and difficulty of the work executed by the contractors, Messrs. Sir John Jackson, Ltd., under the direction of Sir John Wolfe Barry and Messrs. Coode, Son, and Matthews, may be understood from the fact that, in exceptional storms, waves 35 feet in height from trough to crest have been recorded at the mouth of the Tyne, and, owing to the deep water, are propagated almost so far as the pier itself. The old pier met its death-blow during the great gale of January, 1897, when 110 feet of the wall on the seaward side fell outwards. As reconstructed, the North Pier is 2900 feet long, and the entrance to the harbour is now 1180 feet wide. From the foundations on the shale, which was dressed level by divers, the pier has been built of concrete blocks, with granite facing on the outer courses. The depth of foundation below low water of spring tides varied from 28 feet to 44½ feet, being, on the average, about 20 feet more than in the old structure. The width at quay-level is 37 feet, and at low-water level 50 feet. Access is obtained during stormy weather to the lighthouse and machinery for blowing the fog signal at the pier-head through a tunnel, which is constructed under the promenade.

A DESCRIPTION is given in *Engineering* for January 28 of the system of photographic surveying from balloons devised by Captain Scheimpflug, of Vienna. The inventor's experiments have been going on for some years, and formed the subject of a lecture recently given by him before the Physical Society of Frankfort-on-Main. Briefly, the panorama camera consists of a central camera having a horizontal plate and seven inclined lateral cameras surrounding the former. The cameras are rigidly connected with one another, and the shutters are released simultaneously, so that a very large field is secured. Horizontal projections of the inclined negatives are produced by means of a special apparatus, when the resulting panorama views show a centre heptagon surrounded by seven other trapezoidal photographic sheets. The diameter of country represented will be about five times the height of the balloon and camera at the moment of exposure. Photographs are taken at rapid intervals while flying over the ground, and it is desirable that the resulting views overlap by more than half. The nadirs of successive photographs will then be discernible on the same plate. Heights can be obtained from the photographs by means of another apparatus—the zone transformer. The inventor estimates that a survey of German South-west Africa by his system could be accomplished in fifteen years at a cost of 2,000,000*l.*, as compared with a plane-table survey, which would occupy 150 years at an estimated cost of 10,000,000*l.* There certainly seems to be a field for photographic surveying from airships.

THREE new volumes, Nos. 6–8, have been added to the series of books on Egypt and Chaldæa published by Messrs. Kegan Paul, Trench, Trübner and Co., Ltd. They form a second edition, revised and enlarged, of part of Dr. Budge's work on the "Book of the Dead," published under the title of "The Chapters of Coming Forth by Day." The subtitle describes the volumes as an English translation of the chapters, hymns, &c., of the Theban rescension, with introduction, notes, &c. The first edition of Dr. Budge's work, of which the present translations formed the third volume, was reviewed at length in our issue for February 10, 1898 (vol. lvii., p. 337). The translation given in the present series is not merely a reprint from the original issue, for it has been carefully revised and compared with the original texts, and many brief explanatory notes have been added. More than four hundred vignettes, taken from the best papyri, have been reproduced in these volumes at the heads of the chapters, the general contents of which the ancient Egyptian scribes and artists intended them to illustrate. These translations form a representative collection of the various compositions which the Egyptians inscribed upon the walls of tombs and sarcophagi, coffins and funeral stelæ, papyri and amulets, in order to ensure the well-being of their dead in the world beyond the grave. The price of each of the present volumes is 5*s.* net.

The twelfth edition, revised, of Mr. W. T. Lynn's small volume on "Celestial Motions" has been published by Messrs. S. Bagster and Sons, Ltd., price 2*s.* net. The book is an easy introduction to the main facts of astronomical science, and the frequent re-issues enable the author to keep it up-to-date.

Mr. John Browning has issued the fourth edition, re-written and revised, of his concise little book "How to Work with the Spectroscope." The book provides beginners with a handy guide to the use of spectroscopes of various kinds, including McClean's star spectroscope, the microspectroscope, and others; and we welcome it as a simple means of extending the circle of observers of spectroscopic phenomena. The price of the book, with a coloured chart of spectra, is 1*s.* 6*d.*, and without the chart, 9*d.*

OUR ASTRONOMICAL COLUMN.

New Elements for Halley's Comet.—In a note appearing in No. 419 of the *Observatory* (February, p. 104), a set of elements for Halley's comet, deduced by Mr. C. J. Merfield from the observations made since the re-discovery of the comet in September last, is compared with the elements predicted for this return, as follows:—time of perihelion passage, April 19·6394 (G.M.T.), $\omega = 110° 43' 24''$ (=predicted + 68″), $\Omega = 57° 15' 56''$ (=predicted − 16″), $i = 162° 12' 34''$ (=predicted − 8″), $e = 0·967300$ (=predicted + 0·000019″), and $\mu = 46·6723''$ (=predicted + 0·003″). From these elements Mr. Crommelin has calculated the conditions for the comet's transit over the sun, and finds that the first contact should take place on May 18d. 14h. 22m. (G.M.T.) in position angle 264°. Thirty minutes later the centres of the two bodies will be at their least separation, the comet being 62″ south. Last contact should occur at 15h. 22m., in position angle 92°, and the horizontal parallax of the comet will be 54·4″, or 45·7″ relative to the sun. The transit will be visible in Australia, the Pacific, and Asia, and it is sincerely to be hoped that careful and comprehensive observations will be made, for they may provide useful additions to our knowledge concerning the constitution of the denser portions of the comet.

In the same journal Father Cortie discusses the alleged Papal excommunication of Halley's comet ("The Devil, the Turk and the Comet") in 1456, and quotes conclusive evidence showing the story to be a myth.

Studies of Solar and Stellar Spectra.—In two recent communications to the Academy of Sciences (*Comptes rendus*, Nos. 1 and 3), Count A. de Gramont publishes some interesting results as to the occurrence of what he designates *raies ultimes* in the spectra of the sun and various stellar types.

The *raies ultimes* of an element are those lines which persist in the spectrum throughout the range of flame, arc, and spark conditions. Treating different alloys in which the quantity of a component continuously decreases, M. de Gramont finds that the first lines to disappear from the spectrum are the "spark" lines, then those produced in the arc, and lastly the "flame" lines; the most persistent lines are the *raies ultimes*. On the hypothesis that the spectra of the various regions of the sun are dissociation spectra, and that their differences are due principally to variations of the proportions of elements present, M. de Gramont hopes to find indications which will show, more or less, the regions of the sun, and he gives a list of the most persistent and the most sensible lines of seventeen elements already traced in the solar spectrum.

M. de Gramont further points out that the absence of the lines of the metalloids, &c., from the solar spectrum should not be accepted as proof that these substances do not exist in the sun, for he has already shown that the "ultimate" lines of many of them exist in the more refrangible part of the spectrum which our atmosphere absorbs. The "ultimate" lines of gold occur at λλ 2676·0 and 2428·1, and it is suggested that this is the reason that gold has, so far, been considered as absent from the sun.

In the second paper M. de Gramont considers the distribution of *raies ultimes* in different stellar types, having studied for this purpose the Harvard classifications, the numerous publications of Sir Norman Lockyer, and the works of Sir William Huggins. Using the nomenclature of Miss Cannon, in the Draper Catalogue, he finds that these ultimate lines do not occur in the hottest stars, but make their appearance in B8A, the Algolian type, and generally increase in intensity as the lower types are reached. In the *c* division the "ultimate" lines appear at a stage later, and in less numbers, than in the *a* division. M. de Gramont points out that the *c* division corresponds with Sir Norman Lockyer's "ascending series," of which the most characteristic types are the Rigelian and the Cygnian, in which predominates the "test spectrum" or spectrum of enhanced lines. The presence of oxygen and nitrogen lines in the helium stars, lines dissimilar to the ultimate lines, is taken as an indication that in such stars powerful electrical discharges are in action.

M. de Gramont concludes by suggesting that the presence or absence of "ultimate lines" in the spectra of stars may furnish valuable indications of the relative temperatures, or the stage of evolution, of the different types, and is equally applicable to the Harvard classification and the conceptions of Sir Norman Lockyer.

Markings on Mars.—Too late for insertion at the end of his letter on Martian markings as seen with small and large telescopes, published in last week's Nature (p. 397), Prof. Lowell writes:—"It will prove of interest to students of the subject that this optical shattering of lines, due to a large glass, is precisely what M. Antoniadi observed at Meudon in his observations of Mars. He saw in the canals, in place of lines, a tesselated series of dots. His observed mosaic effect is the exact theoretic effect that a large aperture should produce on continuous lines such as the canals, and always does produce in the case of the rings in the images of a star."

Elements and Ephemeris for Tempel's Comet (1873 II.).—In No. 4386 of the *Astronomische Nachrichten* M. Maubant gives the elements and a search-ephemeris for Tempel's second comet, which is expected to pass through perihelion in the near future. The conditions are not favourable for observation.

THE NEW COMET (1910*a*).

Although by its increasing distance from the sun and the earth, and by its apparent recession into the sun's rays, the great comet of 1910 is becoming less popular as a spectacle, the interest among astronomers as to the results accruing from the mass of observations will doubtless continue for a long period. From observers situated in many parts of Europe and Africa we are receiving further evidence of this comet's title to rank among the "great comets" of history.

In sending us the drawing here reproduced, Father Cortie encloses some valuable observations of the comet's appearance on January 26. The drawing was made by Mr. William McKeon, an assistant at the Stonyhurst College Observatory, at 6 p.m. January 26, and in making the observations a small pocket telescope of 1½ inches aperture and 17 inches focal length was employed. The following are Mr. McKeon's remarks concerning the comet's appearance at the time:—"Nucleus of the comet bright and sharp; no merging into the tail, magnitude 2. Nucleus of comet 2° S. and 7° W. of Venus (estimated). The tail terminated at a star of about the seventh magnitude some 8° N. by E. of the head. The star to the right of the comet (N. by W.) was of about the third or fourth magnitude."

Father Cortie identifies this latter star as α Equulei, magnitude 4·1, and thence deduces that the length of the tail, as seen in the small telescope employed, was about 7½°. Naked-eye observations by himself showed the tail extending almost to ε Pegasi, which would make its length 12°; its breadth at the end, he estimated, was about 3°. The sky was perfectly clear, and the tail of the comet was quite a conspicuous object after the head had set, until it was lost in the moonlight. As the drawing shows, there was, in addition to the two main branches of the tail, separated by a dark segment, a fluffy extension on the eastern side; all these features are shown on the photographs taken the same evening, and mentioned in Nature last week.

Further observations were made on January 29, and, although the sky was less clear, the length of the tail was estimated by Father Sidgreaves to be 17° or 18°; the general brilliancy of the comet was less.

Father Cortie also records some observations made by the Rev. J. Rowland at St. Asaph, N. Wales, who directs attention to "a faint general illumination of the sky to the east of the tail, of a width apparently of 10° to 15°, the length of the tail being over 20°. There was also an apparent deviation of the tail to the east between α and γ Pegasi." This confirms the independent observations, made at Stonyhurst and elsewhere, as to the apparent existence of a cloud of particles following the eastern branch of the comet's tail.

Mr. Theodore Kensington, West Malvern, also mentions a similar phenomenon. He says, in a letter dated February 5:—"The comet was a magnificent sight from the Malvern Hills a week ago, and of even more than ordinary interest owing to the glare which was visible, in apparent connection with it, on its southern side. This glare was best seen on the evenings of January 29 and 30, but it was also visible last Wednesday and Friday."

E

1910 I 26, 6pm
W McK

The comet as seen at Stonyhurst on January 26 by Mr. McKeon.

Mr. Kensington further states that the glow was like that from a distant city or an aurora, but that it was not terrestrial was shown by its setting with the stars. It was like an inverted **U** the right side, bounded by the comet and the square of Pegasus, reaching nearly to Saturn, while the left (south) side descended almost perpendicularly, but with a slight trend inwards, to the visible horizon. The distinction between the bright background on the one side of the comet and the dark sky on the other side was quite marked, but after January 29 there was a darker band of sky between the comet's tail and this glow.

Miss Eleonora Armitage, writing from Dadnor, Herefordshire, states that the glare seen in the neighbourhood of the comet was the zodiacal light, which showed particularly well on January 29. She adds:—"The tail of the comet was well defined on the west side, reaching a little beyond and above α Pegasi, as seen with the naked eye; on the east side it could be traced almost so far as γ Pegasi, but along most of this side the edge was very indefinite, owing to the light practically blending with that of the zodiacal light, both having apparently the same degree of luminosity. β Aquarii could be seen through the tail a little above the nucleus of the comet. The next evening, January 30, the comet was much fainter, but the tail could still be traced for nearly 30°, while the zodiacal light stretched up in a bright cone, the apex almost reaching to Saturn. When seen again on February 4 the northern movement of the comet had removed it from the track of the zodiacal light, so that the two lights appeared to be separated by a segment of dark sky, the eastern edge of the curved tail being now nearly as clearly defined as the western."

Reports from other observers indicate that the zodiacal light has been well seen on several occasions during the past fortnight. Dr. F. J. Allen saw it and the comet, under ideal conditions, from the Mendip Hills on January 30, and suggests that the "glare" near the comet as seen by other observers was doubtless the light. A correspondent ("E. W. P.") at Ross, Herefordshire, also states that "the zodiacal light was distinctly seen this evening at 6.45 (February 4), whilst the tail of the 'daylight' comet seemed to reach further than ever."

Dr. Allen's observations of the comet are of especial interest, for he remembers distinctly the comet of 1858 (Donati's), and has seen all the bright comets since, and states that, as he saw it on January 30, 1910a is the only one which can be compared in effect with Donati's. The intermediate ones, though brighter than the present one, were poor little things in apparent size. He suggests that the estimates of its apparent size have erred on the side of cautiousness. As he saw it at Cambridge, during the early days of its appearance, his estimates agreed with the usual ones; but as seen from the Mendips, smoke, gaslamps, and clouds being absent, and the night exceptionally clear, the tail reached beyond and included α Pegasi, and then took a more pronounced curve to the left. He estimates its length as 40°, and suggests that, had the zodiacal light been absent, the tail might have been traced further, for the light rendered its S.E. limit indefinable; his observations extended for more than an hour, between 6 p.m. and 7.30 p.m. Prof. R. A. Gregory, observing at Chichester on January 29 and 30, found that the tail was certainly 30° long, whilst M. Giacobini reports (*Comptes rendus*, vol. cl., No. 5, p. 263) that, as seen by the naked eye at the Paris Observatory, on January 29, its length exceeded 45°. M. Chofardet, at Besançon, states that on January 27 the tail was 25° long, and, curving towards the south, mixed its light with that of the zodiacal light.

In a further communication, Mdlle. de Robeck, observing at Inistioge, Kilkenny, states that on January 29 the comet appeared very much in the same way as shown in Mr. Rolston's sketch in last week's Nature, but the tail seemed to reach higher, and swept upward nearer to α Pegasi. After Venus had set, the tail of the comet was seen like a great search-light sweeping the sky, and the fainter stars below Pegasus were seen glittering brightly through it; the night was exceptionally clear at Inistioge. Mdlle. de Robeck also states that, before the comet became such a noticeable object, the country people around Inistioge took Venus to be the much-talked-of object, and saw in it a portent of dreadful calamities. That the Earl of Crawford's suggestion (Nature, January 20, p. 349) was an urgent one is proved by the reports of "comet scares" in Russia, Turkey, and other countries, occasioned by the sudden and unexpected appearance of 1910a. It certainly would be well to prepare the native minds for the apparition of Halley's comet when, as Mr. Cowell thinks it will, it becomes sufficiently bright and large to attract general attention.

Mr. Keeling, of the Helwan Observatory, Egypt, reports that the comet (1910a) was observed on several evenings at Helwan, Egypt, and photographs of it were obtained on January 24, 25, 27, and 28; the camera employed has a Cooke lens of 4 inches aperture and 28 inches focal length. Naked-eye observations on January 27 and 28 showed the tail to be 24° to 25° in length.

A telegram from Dr. Aitken (*Astronomische Nachrichten*, No. 4386, p. 292) states that Dr. Albrecht finds the sodium lines in the spectrum of the comet to be so displaced as to indicate a recession of ·66 km. per sec. in the line of sight. As the position of these lines has now, apparently, been measured with sufficient accuracy to justify a definite statement as to "shift," it seems very improbable that the yellow lines observed are due to helium, unless two sets of such lines have been observed, and there is no suggestion of this. In this regard Mr. Hinks writes to us disclaiming the statement attributed to him by a reporter, as mentioned on p. 410 last week, and states that "there is no truth in this reported unconventionality."

Spectroscopic observations of the comet, made at Meudon, are described by MM. Deslandres, Bernard, and d'Azambuja in No. 5 of the *Comptes rendus* (vol. cl., p. 253).

Using the prismatic cameras previously employed on the Morehouse and Halley comets, photographs were obtained on January 22, 24, 25, 27, 29, and 30. Orthochromatic, red-sensitive plates were used, and the best negative of January 22 was secured with an exposure of five minutes. This shows a brilliant nucleus giving a continuous spectrum from λ 700 to λ 420 and several condensations.

The brightest condensation is at λ 590, and is recognised as due to sodium; it shows a complete monochromatic image of the comet with a well-defined tail, brightest at its edges and extending to a distance of 20′ of arc from the head. The hydrocarbon bands at λ 560 and λ 470 are also recognisable. In addition to these, there are two condensations at λ 620 and λ 700 extending some 10 minutes of arc into the tail, and not previously recognised in cometary spectra.

The later photographs show the progressive differences which have been observed in other comets (*e.g.* that of 1882) having small perihelion distances; the sodium lines faded gradually, while the hydrocarbon bands became more intense, and those due to cyanogen made their appearance.

On January 29 and 30 the sodium bands were absent, the hydrocarbon bands (λλ 565, 517, 474) stronger than before, the continuous spectrum extended into the ultraviolet, and the cyanogen bands at λλ 388, 387, 386 were complete and intense.

The wave-lengths given now are, necessarily, only approximate, but other photographs, taken at the same time with a slit spectrograph, will give finer values, which are promised in a later publication.

Ordinary photographs were also secured, and those taken on January 22 show a fine, curved tail divided into two "antennæ" with a dark line down the centre. On January 29 a supplementary tail was shown, nearly as intense as the first, and making an angle with it of about 25° towards the south.

Observations made with a simple Nicol on January 29 indicated that the light from the tail was strongly polarised in the plane containing the sun, the comet, and the earth.

The *Astronomische Nachrichten* also contains the elements and ephemeris by Dr. Kobold, from which we gave an extract last week, and the records of a number of observations made at the Continental observatories. At the Bothkamp Observatory on January 23, 4h. 50m. (M.T. Bothkamp), Dr. Schiller found the comet to be of the first magnitude, and to have a sharply defined nucleus of 4″ diameter. He reports, also, that the head was very similar to that of Donati's comet shown in Fig. 153 of the third edition of Newcomb-Engelmann; the position-angle of the medial line of the two tails was 40°. On January 23 the comet was fainter, but, to the naked eye, the tail appeared to extend to a distance of 15°.

Later elements and ephemeris are published in Circular No. 119 from the Kiel Centralstelle, and are based on observations made on January 20, 23, 26, and 30; they are as follows:—

Elements.

T = 1910 January 17·1235 (M.T. Berlin)

$$\left.\begin{array}{l}\omega = 320^\circ\ 58{\cdot}64' \\ \Omega = \ 88^\circ\ 47{\cdot}14' \\ i = 138^\circ\ 47{\cdot}12'\end{array}\right\}1910{\cdot}0$$

$\log q = 9{\cdot}11153.$

Ephemeris (Midnight, Berlin).

1910	R.A. h. m.	Decl. ° ′	Magnitude
Feb. 10	21 54·4	+ 7 40·8	4·0
12	21 57·2	+ 8 24·8	
14	21 59·8	+ 9 5·5	4·4
16	22 2·3	+ 9 43·5	
18	22 4·6	+10 19·1	4·8
20	22 6·8	+10 52·8	
22	22 8·9	+11 24·9	5·0

The magnitudes are based on the observation that the magnitude on January 27 was 2·0, and are independent of any physical changes in the comet itself.

We notice that the misnomer "Drake's comet" is still being employed. As this is likely to lead to subsequent confusion, it would seem as well to refer to this object as the "Worssell-Innes comet, 1910*a*," Messrs. Worssell and Innes, of the Johannesburg Observatory, having been the first to make and record any definite observations of it.

A FINNISH ETHNOLOGICAL EXPEDITION TO BRITISH PAPUA.

ABOUT the middle of this month Dr. Gunar Landtman, lecturer in sociology at the University of Helsingfors, will leave London for an ethnological expedition to British Papua. In 1904 Dr. Landtman attended the Martin White lectures on sociology that were given in the University of London by Prof. E. Westermarck and those on ethnology by Dr. A. C. Haddon. In 1905 he wrote his doctor's dissertation "On the Origin of Priesthood," and in 1909 published a thesis on "The Primary Causes of Social Inequality." Dr. Landtman will make the island of Badu, in Torres Straits, his headquarters; thence he expects to proceed to Saibai, and later to that portion of the mainland of British Papua which faces Torres Straits, and is known to the natives as Daudai, and, gradually working his way eastwards, he will eventually study the natives of various islands in the delta of the Fly River. Very little is known about this district, and it is important that it should be investigated before the natives are further modified by contact with the white man.

The ethnography of the islanders of Torres Straits has been carefully described by the members of the Cambridge Anthropological Expedition to Torres Straits, and it is fortunate that their results will now be linked on to the mainland of New Guinea, for there is no doubt that the western and eastern islands of the Straits were populated by various emigrations from the mainland. Friendly relations have always been maintained between the islanders and the mainlanders, and a good deal of simple trading has taken place between them; but most interesting of all is the culture influence that formerly extended from the mainland to the islands. In the island folk-tales we hear of the introduction of ceremonies (in most of which masks were employed) by men who seem to have been actuated by a missionary spirit, and the most important of the hero-cults of the central and eastern islands appears to have come from New Guinea. It is Dr. Landtman's intention to endeavour to trace these to their sources.

Totemism is known to occur in the district about to be investigated, where, for some unexplained reason, plant totems are more abundant than animal totems. We may also expect to learn something about the origin of the hero-cult of the islanders, but we do not in the least know whether these legendary persons are heroes in their own country. To the east, along the shores of the Papuan Gulf, the Rev. J. Holmes has discovered a belief in gods who appear to be apotheosised ancestors. It is remarkable that this is the only district of British Papua from which gods have been recorded, but we do not know the western limit of this belief.

A careful study of the social customs and religious beliefs and practices of the natives of Daudai and of the Fly River delta will reveal to us whether their totemism is in a typical condition or whether it is being modified by superior cults, and it is very desirable that a metamorphosis of this kind should be accurately recorded. There are many other problems connected with this interesting region that require elucidation, and we wish Dr. Landtman every success in his undertaking. Dr. Landtman would like to spend at least two years in the field, but is at present uncertain whether he will not have to content himself with one year. On his return he proposes to spend about nine months in Cambridge in order to work out his results, which will be published in English.

RECENT WORK OF GEOLOGICAL SURVEYS.[1]

II.

South Africa and Australasia.

THE Geological Commission of the Cape of Good Hope has issued Sheets 33 and 41 of the geological map of the colony on the scale of 1/238,000, covering the country to the north-east and south-east of Prieska, and just reaching to De Aar. A long stretch of the Orange River wanders through Sheet 41, and its excavating action has here and there revealed the rocks below the prevailing Dwyka series. To the north-west the ground rises, and the Transvaal system, with the dolomites, appears in force. Sheet 33 is a remarkable performance considering the small staff of the Survey, and shows the sinuous outcrops of the Karroo doleritic sheets invading the Ecca shales and the Dwyka series over 3000 square miles of country. Complicated inliers of the older rocks appear in the north-west. The country shown in these maps is described in the Annual Report of the Geological Commission for 1908 (1909). The ring-like outcrops of the igneous sills in Sheet 33 are explained by the presence of tectonic basins, whereby an escarpment of dolerite, facing outwards, encloses an area of overlying Ecca shales. On p. 111 of the report Mr. A. L. du Toit describes the kimberlite and allied pipes and fissures in the Prieska-Britstown region, giving interesting sections to show the typical dome-formation in the strata where the pipes have broken through. A careful study has been made of the inclusions of garnet-granulite and eclogite that are so characteristic of the pipes, and the author shows that they have been brought up from rocks, possibly of sedimentary origin, that were metamorphosed at considerable depths. Dr. A. W. Rogers (p. 135) has re-examined the Tygerberg near Prince Albert Village, and continues to maintain, in opposition to Dr. Sandberg, that the structure is that of an ordinary anticlinal (see NATURE, vol. lxxvi., p. 423).

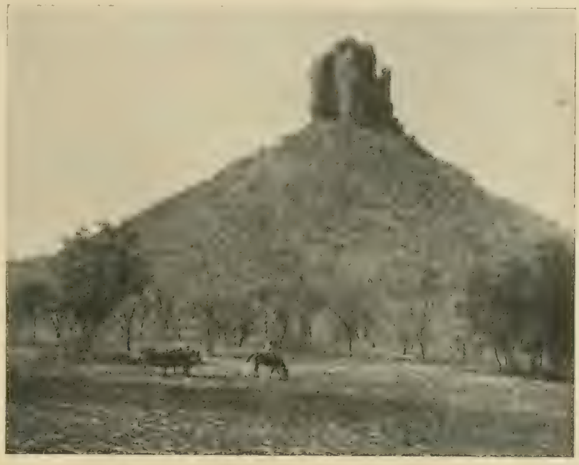

Fig. 1.—Kopje of Waterberg Sandstone, country west of Potgietersrust, Transvaal.

The Geological Survey of the Transvaal Mines Department shows great vitality. The large areas mapped and reported on in a year may be seen in the maps recording progress, appended to the reports for 1907 and 1908. In the report for 1907 (received in July, 1909) attention is properly directed by the Secretary for Mines to the inter-relation of the so-called scientific and economic duties of the Survey. From time to time a brief defence of this kind becomes necessary; but it requires some delicacy, since few geologists would like to set down in print the extraordinary ignorance of earth-structure prevailing among prospectors and "practical men." Support could always be given, however, to colonial surveyors by those in European countries, who know how small details of dip, unconformity, or rock-sequence shown upon their laborious large-scale maps, or perhaps revealed by palæontological studies, prove again and again of service to inquirers in directing their operations or in diverting them to more profitable fields. Geological surveys play, moreover, a high educational part in explaining the features and historical development of a country, and it should be the pride of a growing nation to allow natural sciences to take the place that has been accorded to dead languages in more conservative lands. In the report for 1907 Mr. A. L. Hall describes the geology of the Haenertsburg goldfields, and shows (p. 53) how the stratified rocks of the Pretoria series have been metamorphosed by the Bushveld granite, yielding every variety of type, from bedded shales with new minerals to strongly marked schists and gneisses. He urges that, while pressures have operated during this contact-alteration, dynamic metamorphism is insufficient to account for the phenomena. The rocks illustrate the spread of material along schistose surfaces perpendicular to the pressure (Rieke's principle), and the production of minerals of small molecular volume (Lepsius's law of volumes). We should like, however, to hear more of the relation of the foliation-planes of the most altered types of shale to the original bedding, since we believe that these features are frequently coincident in highly altered contact-rocks. Chromite occurs concentrated in bands in the hypersthenite of the Lydenburg district (p. 59), and similar bands are described by Mr. Humphrey (p. 89) in the norite of Kroonendal, near Rustenburg. Mr. Hall has been able to extend his conclusions as to the potency of contact-metamorphism to the country south-west of Rustenburg (p. 66). Mr. Kynaston reports on the cassiterite deposits in the Waterberg district, where the hilly ground falls northward to the Limpopo. The ore is found in granite in pipes of circular or oval section, which are formed of highly altered granite, with ore concentrated towards their margins (pp. 97 and 100). These are compared with smaller occurrences in New South Wales. Our knowledge of Waterberg is extended by Messrs. Kynaston and Mellor in the report for 1908. The Waterberg Sandstones, which are somewhat like our Old Red Sandstones, form characteristic tower-like kopjes (Fig. 1). The pipes of tin-ore occur on each side of the granite ridge that runs north-west near Zaaiplaats, and are already being well developed (p. 46). In a country where fossiliferous strata are so rare, petrography naturally plays a large part, and the metamorphic zones of both the older and younger granite receive careful description in various papers in this report. The younger granite of Waterberg, a handsomely red rock, yielded boulders to the Upper Waterberg series, but continued to send off-shoots into this series in the Hoekbergen and the Middleburg district to the south-east. Deposits of manganese, zinc, and lead ore, and of gold are described by Mr. W. A. Humphrey from the Marico district away west; the Malmani goldfield, which has been worked sporadically, lies not far from Mafeking. These reports, which are priced at only 7*s.* 6*d.* each, are, as usual, well illustrated by landscapes and by coloured maps and sections. The Survey has also issued a special octavo memoir on the Waterberg tinfields (1909, price 7*s.* 6*d.*), in which the conclusions and illustrative sections are reproduced in a convenient form. The ore-bodies are discussed in detail, and a small example of the remarkable cylindrical pipes is well shown in a photograph in Plate viii.

---

[1] Continued from p. 382.

The Annual Report of the Geological Survey of Western Australia for 1908 (Perth, 1909) contains an account of the phosphatic deposits of Christmas Island, by Mr. H. P. Woodward. The travertine that has become phosphatised from above is about 2 feet thick, and is ascribed to the evaporation of capillary waters, which bring calcium carbonate in solution from underlying shelly sands. This kind of rock may be matched in South Africa and in other countries where rains are only seasonal. The fundamental rocks appear along the coast and in bold hills at the north and south ends of the island. They are granite, gneiss, and schist, with basic dykes rich in magnetite. A large number of analyses of the phosphatic beds and a map of the island are supplied. The Survey has reprinted three earlier bulletins on the Pilbara goldfield in a compact little volume (1908), with a large number of folding maps and plans. This goldfield is in a tropical region east of the Yule River. The gold occurs in quartz-reefs, mainly in a green schist series, which is probably of igneous origin. Alluvial tin-ore is also worked, and has been traced to local granite masses. Bulletin No. 32 (1908, price 2*s.*) is also a guide to miners in special districts. The tests given for the ready discrimination of ores are an excellent feature, and that on p. 12, for cassiterite in a concentrate of similar heavy minerals, is new and fascinating. Native tin has been found (p. 22) in the Greenbushes tinfield in the south-west of the State, and is attributed to the action of bush-fires on surface ores. Tantalite is of growing importance in Australian fields. Mr. Gibb Maitland pointed out some years ago that the laterite of the Greenbushes area is being denuded away. Mr. H. P. Woodward now states (p. 31) that the deposit appears in places as a zone between two alluviums. It has resulted from the alteration of rocks as diverse as diabasic schist and alluvium, under conditions of climate that may have been recurrent, but which do not now prevail. Bulletin No. 35 (1909) deals with the gold and copper deposits of the Phillips River Goldfield, about 150 miles east of Albany. The basic schists of the region are capped by laterite and the serpentines by magnesite (p. 10); bands of laterite, moreover, traverse the country like lodes, but are believed to be only the weathered tops of basic igneous dykes (p. 12). Certain andalusite-sericite schists are attributed to the alteration of granites rich in soda and alumina (pp. 21 and 23). The coloured map of Ravensthorpe is impressive, with its grand series of basic dykes running across the granite from a greenstone region in the north-west. These dykes can usually be recognised across country by the rich red soil upon them. Bulletin No. 37 (1909), by Mr. C. G. Gibson, is of imperial importance, being a description of the geology along the proposed transcontinental line of railway through Australia from west to east, so far as the route lies in the State of Western Australia. The illustrations of camels procuring water at small holes in bush and desert are not encouraging to the townsman, but will probably serve only as a stimulus in these lands of healthy enterprise. These remarkably cheap reports, in which maps and memoirs are combined, must be of immense service in a country intent on understanding its resources.

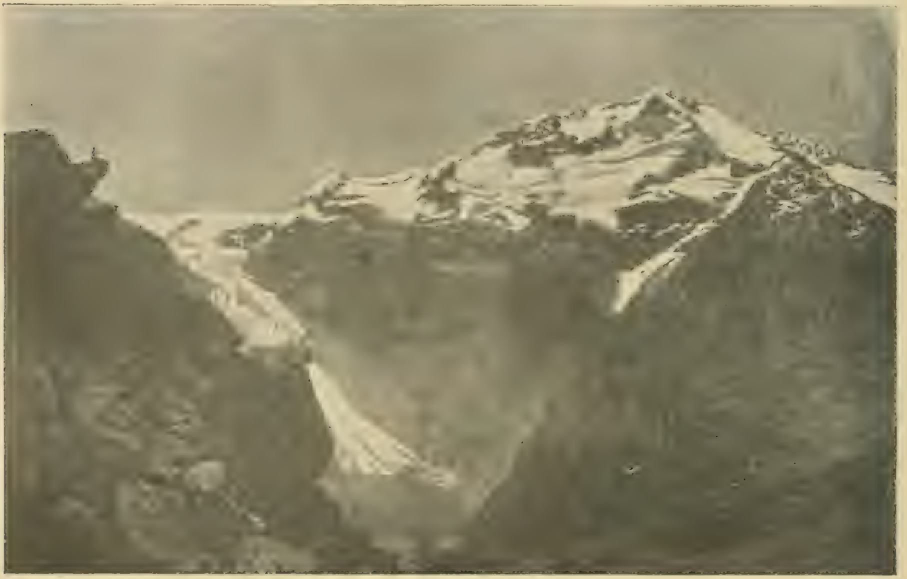

FIG. 2.—Mount Lambert, New Zealand Alps, with glacier broken by a precipice in its descent.

The Secretary for Mines for South Australia issues a review of mining operations in the State for 1908 (Adelaide, 1909). Mr. H. Brown describes certain phosphate deposits (p. 21), which have a general interest because of their interstratification with Cambrian clays, sandstones, and limestones. It is suggested, as in the case of the Welsh beds, that the calcium phosphate results from the abundance of organisms which utilised it in their shells in Palæozoic times. At present these deposits are overshadowed commercially by Christmas and Ocean Islands.

The Geological Survey of New South Wales issues a report and map, by Mr. E. C. Andrews, on the Drake Gold and Copper Field, where folding at the close of Carboniferous times was accompanied by successive intrusions of granitic magmas of decreasing basicity. Dioritic dykes then broke through, with which the gold, copper, lead, and silver ores are associated. The mineral features are thus of early Mesozoic age (p. 6). The porphyritic hornblende-granite of Malarra (p. 9), a member of the earlier intrusions, seems of unusual attraction as an ornamental stone. There is a somewhat exceptional mingling of sound geology and mining applications in this compact report. The Survey shows a keen interest in palæontology in its Records, vol. viii., part iv. (1909, price 7*s.* 6*d.*). Mr. R. Etheridge, among other contributions by him, describes a large tubular organism from Gotlandian strata, allied to the Carboniferous Mitcheldeania. Dr. A. S. Woodward adds to our knowledge of the labyrinthodont Bothriceps. Mr. G. W. Card continues his painstaking determinations of the minerals of the State, and the analyst, Mr. J. Mingaye, supplies details of importance to all chemists as to the modes of separation of thoria from monazite (p. 276).

Mr. W. E. Cameron has written for the Queensland Geological Survey a second report on the Etheridge Goldfield (Brisbane, 1909), where the ores occur in reefs in granite, or associated, like those of the Drake Field in New South Wales, with basic dykes, which here penetrate schists. The Survey has also issued a third edition of a very useful geological and mining map of Queensland, on the scale of 1 inch to forty miles.

In Bulletin No. 6 of the New Zealand Geological Survey (1908, price 2*s.* 6*d.*) Mr. P. G. Morgan describes the southern part of North Westland, on the western coast of the South Island. The author feels strongly that high ground existed in the oceanic area to the west down to the commencement of Pliocene times (pp. 34 and 37), and that this land disappeared only when the present Alps of New Zealand rose towards their maximum height. A relic is believed to remain in the Carboniferous Greenland series (p. 96), which is folded almost at right angles to the trend of the Southern Alps. The conglomerates of the Oligocene or Miocene Koiterangi series (p. 102) are at first glacial and then fluviatile, and their pebbles may have descended from the old western highlands. The modern glacial features of the interior furnish material for several striking photographs (Fig. 2).

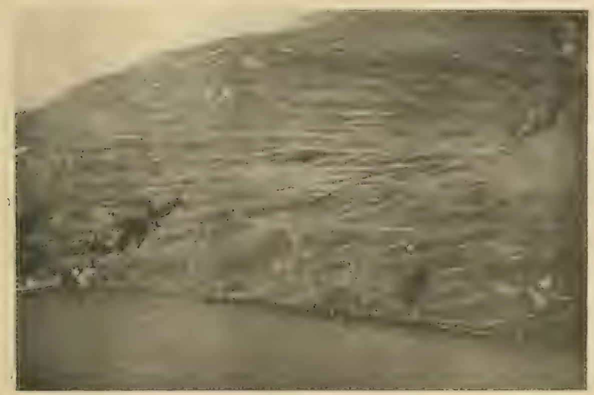

FIG. 3.—Ice-carved terraces on slope of Ben More, Western Otago.

Prof. James Park, in Bulletin No. 7 (1909, price 2*s.* 6*d.*), has an equally grand field in the Queenstown subdivision of western Otago. Queenstown lies on the winding Lake Wakatipu, which is fifty miles in length, and close against serrated Alpine ranges. The main theme of this splendidly illustrated monograph is the evidence for widespread Pleistocene glaciation in the South Island. All the signs of confluent glaciers, developing into an ice-sheet, are here brought together in an argument that appears complete. The decline of the ice seems to have been as rapid as in Europe, giving rise to "unparalleled fluviatile activity" (p. 41). The late Pliocene elevation of the country is held to have had considerable influence on the refrigeration, and the Pleistocene subsidence was accompanied by recession of the ice. Striated surfaces, boulder-clays, drumlins, eskers, and all the features familiar in our hemisphere, are here illustrated from 45° south latitude. Especially remarkable, however, are the terraces carved out on Ben More above Lake Luna, in a quartzose mica-schist (p. 31), which Prof. Park believes to be unique features of ice-erosion (Fig. 3). The author contributes a short essay on ice-flow and the excavating powers of glaciers. References to the structure of glacier-ice and to experiments on its plasticity would have rendered this more complete, but enough is said to excite interest. The bulletin concludes with an account of local gold-mines, and the maps cover the important areas in which alluvium has been worked, or in which the quartz-reefs seem of promise. As usual, for beauty of illustration and the excellent production of the accompanying maps, these New Zealand bulletins remain unsurpassed.

G. A. J. C.

THE LINNEAN SOCIETY'S DISCUSSION ON THE ORIGIN OF VERTEBRATES.

DURING the past fifty years one of the chief tasks to which zoologists have applied themselves has been the reconstruction of the phylogeny of the animal kingdom in accordance with the principles of evolution laid down by Charles Darwin. This task is still far from being completed, although no one can doubt that very substantial progress has been made. The evidence is still very imperfect, and every increase of knowledge makes more clear the need for extreme caution in drawing conclusions. When we think of the familiar comparison of the animal kingdom to a luxuriantly branching tree of which only a few of the topmost twigs are known to us in the living condition, while at the same time we are only able to recover from the past the most fragmentary records of the millions of extinct forms, we are able to realise why it is that most zoologists at present refuse to commit themselves to any particular theory of the origin of vertebrates. Of course, numerous theories have been put forward from time to time, but none has met with anything like general acceptance, and there appears to be a widespread feeling that in the present state of our knowledge any such theory is somewhat premature. The discussion of the subject, however, cannot fail to be of use in stimulating thought, and the debate which has occupied the last two meetings of the Linnean Society has naturally aroused considerable interest.

Dr. Gaskell, as opener, expounded, in his usual brilliant style, his own particular theory of the origin of vertebrates from an arthropod ancestor. This theory has already been before the scientific public for many years, but has met with little favour amongst professional zoologists, most of whom find it impossible to believe that a highly specialised Limulus-like arthropod could have given rise to such a very different type of organisation as the vertebrate. Dr. Gaskell, as is well known, bases his argument mainly upon his study of the Ammocœtes larva of the lamprey, between which and the king-crab he endeavours to draw a very close comparison.

The keynote of this comparison lies in the central nervous system. The ventricles of the brain, with their lining epithelium, are supposed to represent the arthropod stomach, and the central canal of the spinal cord the intestine. The infundibulum is the ancestral œsophagus, and the neurenteric canal the ancient vent. Around this tubular foundation the various ganglia of the arthropod nervous system have become arranged to form the nervous tissue of the vertebrate brain and spinal cord. The original functions of the ancestral alimentary canal have disappeared, and it has been finally replaced by an entirely new structure developed from a respiratory chamber in some palæostracan ancestor. This theory, of course, lands us in a serious difficulty from the embryological point of view, for if we accept it we must admit that the germ-layers in arthropods and vertebrates are not homologous—that the epiblast of the one becomes the hypoblast of the other, and *vice versa*. Dr. Gaskell does not find this difficulty by any means insuperable, and, as part of his argument, runs a tilt against the germ-layer theory as at present accepted. In this he was largely supported by the subsequent observations of Dr. Gadow and Prof. Stanley Gardiner.

The debate naturally centred around Dr. Gaskell's theory, which was discussed from the standpoints of embryology, comparative anatomy, palæontology, physiology, and even psychology, the subsequent speakers being Prof. MacBride, Prof. Starling, Mr. Goodrich, Dr. Gadow, Dr. Smith Woodward, Prof. Dendy, Sir Ray Lankester, Dr. Chalmers Mitchell, Prof. Stanley Gardiner, the Rev. T. R. R. Stebbing, and the president (Dr. D. H. Scott). Dr. Gaskell replied at length at the end of the second evening.

It is impossible in this article to give more than a very general account of the course of the discussion, and this is the less necessary as the Linnean Society has announced its intention of publishing it in full, while Dr. Gaskell's views have recently been given to the world in book form.

For reasons which have already been indicated, no definite theory was put forward as a rival to that of Dr. Gaskell, though probably no competent zoologist would have much difficulty in formulating such a theory. Amphioxus, however, loomed large, especially in the remarks of Mr. Goodrich. Dr. Gadow, whose remarks, on the whole, tended strongly to support Dr. Gaskell, expressed the opinion that the attempts which have been made to bring Amphioxus into line have not been successful, but it was pointed out that this animal, though in some respects undoubtedly modified—according to Sir Ray Lankester, even degenerate—nevertheless more nearly resembles a primitive vertebrate than any other animal living at the present day. Probably no zoologist now claims it as being in the direct line of descent of the higher vertebrates from their invertebrate ancestors, but it has gone off on its own little side-track for only a short distance from the starting point. In many respects it retains primitive vertebrate characters, such as the notochord, the numerous gill slits, and the comparatively undifferentiated central nervous system (which may, however, be partly explained as due to degeneration). It shows hardly any sign of cephalisation, and no trace of the paired sense organs which form so dominant a feature of the organisation in higher vertebrates. It represents an altogether lower grade of organisation than the lamprey or even the Ammocœtes larva, yet, as Dr. Goodrich clearly showed, there is no difficulty in deriving the lamprey from an Amphioxus-like ancestor by a normal process of evolution in which cephalisation has played the leading part. If, however, we accept an Amphioxus-like ancestor as the starting point of the vertebrate phylum, we must put the arthropod theory out of court at once, for many of the structures upon which Dr. Gaskell lays much stress as evidence in support of his theory, such as the lateral and pineal eyes, have not yet appeared at the commencement of the vertebrate series, and must have been evolved within the limits of the phylum.

As to what preceded the Amphioxus-like ancestor of vertebrates, zoologists, as already observed, refuse to commit themselves to an opinion. They await more evidence. In the meantime, it is pointed out that the possession of nephridia with solenocytes, identical with those of certain chætopod worms, suggests annelidan affinities, and that the worm-like Balanoglossus, with its Amphioxus-like gill slits but very dubious notochord, must also be taken into account, while the evidence of embryology points to some far remote relationship between Amphioxus, Balanoglossus, and the echinoderms.

The chief difficulty in the way of comparing the vertebrate with the annelid lies, of course, in the reversal of the surfaces which such comparison implies. In the annelid the principal part of the central nervous system lies ventrally beneath the gut, in the vertebrate it lies dorsally above the gut. Dr. Gaskell maintains that the old way of getting over this difficulty by turning the animal upside down and making the dorsal surface of the vertebrate represent the ventral surface of the invertebrate ancestor is now universally discredited. Yet we find Prof. Sedgwick saying in his "Text-book of Zoology," so recently as 1905, that it is quite clear that the dorsal surface of the vertebrate corresponds to the ventral surface of other cœlomates, a view which is strongly supported by the history of the ascidian tadpole, in which the mouth is dorsally situated, instead of ventrally, as in higher chordates.

A considerable amount of detailed criticism of Dr. Gaskell's theory was, of course, brought forward during the discussion. Prof. MacBride pointed out that the skin of the primitive vertebrate must have been ciliated, while in the arthropod the entire organisation is dominated by the production of a thick, chitinous cuticle. He also spoke in defence of the germ-layer theory, and criticised Dr. Gaskell's explanation of the hollow gastrula stage of the arthropod Lucifer, the existence of which seems clearly to indicate that the two primary layers of arthropods are identical with those of vertebrates.

An attempt was also made by the present writer to show that Dr. Gaskell's interpretation of the lateral and pineal eyes of vertebrates as the homologues of the lateral and median eyes of arthropods would not bear the test of critical examination. The same speaker endeavoured to explain the hollow tubular character of the vertebrate central nervous system as a comparatively recent adaptation to the requirements of the vertebrate organisation, in which the necessary increase of surface is brought about by the familiar process of folding. Dr. Chalmers Mitchell directed attention to the mode of origin of the nervous system in various invertebrate groups, and scored a point against Dr. Gaskell by his reference to the recent conclusions of Prof. C. Judson Herrick with regard to the arthropodan nervous system.

Prof. Starling maintained that, as regards the principles which must guide any research into the phylogeny of our race, a physiologist has as good a right to be heard as a comparative anatomist, and he thinks that "it is as difficult to conceive that the vertebrate was evolved from a primitive worm-like organism which shot up past the more highly developed Arthropoda as it is to believe that mankind is destined to be replaced by some beast that is now being evolved from lower groups in the depths of the sea." The observations of Dr. Smith Woodward, on the other hand, which dealt with the subject from the palæontological point of view, seemed to indicate that the process of evolution takes place very much in the way which Prof. Starling finds it so difficult to imagine. Moreover, the claims of the ancient ostracoderms to arthropodan affinities, upon which Dr. Gaskell lays so much stress, seem to be extremely dubious; they were probably highly specialised forms, perhaps related in some respects to the lampreys.

Though unable to accept his views on the subject before the meeting, Sir Ray Lankester voiced what must have been a very general feeling amongst those present in expressing his appreciation of Dr. Gaskell's observations.

ARTHUR DENDY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor gives notice that the Sadlerian professorship of pure mathematics is vacant. The election to the professorship will take place on Monday, February 28. Candidates are requested to send their names to the Vice-Chancellor on or before Saturday, February 19.

The office of superintendent of the museum of zoology is vacant by the resignation of Prof. Punnett. The stipend at present attached to the office is 200*l*. per annum. Applications should be sent to the chairman of the special board for biology and geology (Prof. Langley, The Museums, Cambridge) on or before March 7.

Mr. J. C. F. Fryer has been elected to the Balfour studentship from March 25.

A grant of 200*l*. has been made from the Balfour fund to Mr. C. F. Cooper, for an investigation into the Tertiary vertebrate fauna of India, and a grant of 40*l*. to Mr. K. R. Lewin, in furtherance of his work in protozoology to be carried on abroad.

The following grants were made in the year 1909 from the income of the Gordon Wigan fund at the disposal of the special board for biology and geology:—(*a*) 12*l.* 10*s.* to Dr. D. Sharp; (*b*) 50*l.* to Prof. Langley, for the purchase of a Sändstrom kymograph and accessory apparatus; (*c*) 50*l.* to Mr. A. G. Tansley, that the botanic garden syndicate may continue to offer facilities for plant-breeding experiments; (*d*) 50*l.* to Mr. H. Scott, for the care and development of the collection of insects; (*e*) 25*l.* to Mr. H. H. Thomas, for collecting fossil plants in east Yorkshire with the view of a thorough investigation of its Jurassic flora.

OXFORD.—Dr. Henry Wilde, F.R.S., has offered the University the sum of 600*l.* for the foundation of an annual lecture on astronomy and terrestrial magnetism, in honour and memory of Edmund Halley.

A DEPARTMENT of experimental biology has, says *Science*, been organised in the Rockefeller Institute. Prof. Jacques Loeb, of the University of California, has been elected head of the department.

THE total amount received and promised up to the present for the building and endowment fund of Bedford College (University of London) is 47,700*l.*; a further 12,300*l.* is required before the buildings can be begun.

THE twelfth annual dinner of the Central Technical College Old Students' Association will be held at the Trocadero Restaurant, Piccadilly, W., on Saturday, February 12. Among the guests will be Sir Philip Magnus, M.P.

IT is announced in *Science* that the late Mr. D. Ogden Mills, of New York City, bequeathed 20,000*l.* to the American Museum of Natural History, 10,000*l.* to the New York Botanical Garden, and 5000*l.* to the American Geographical Society of New York City. From the same source we learn that Mr. J. S. Huyler, of New York, has given 4000*l.* to Syracuse University.

IN the Journal of the Royal Statistical Society for January Dr. W. Garnett discusses briefly the statistics of certain scholarship examinations of the London County Council. Returns of marks were available for about 10,000 boys and 10,000 girls, in round numbers, in the subjects of arithmetic and English, and Dr. Garnett has drawn up diagrams and formed models illustrating the correlation between the marks in the two subjects for each sex. Some interesting points are brought out very clearly in quite an elementary way, the distributions of frequency in the two cases presenting some conspicuous differences as well as some general similarities. In both sexes, for example, the weaker candidates on the whole did better in English than in arithmetic, and the stronger candidates better in arithmetic than in English; but while boys gaining more than half-marks on the entire examination began to do better as a whole in arithmetic than in English, the same could only be said of the girls attaining 67 per cent. of the total marks or more, *i.e.* it was only the comparatively exceptional girls who did the better in arithmetic.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 3.—Sir Archibald Geikie, K.C.B., president, in the chair.—F. D. **Thompson**: The thyroid and parathyroid glands throughout vertebrates.—Prof. E. A. **Minchin** and J. D. **Thomson**: The transmission of *Trypanosoma lewisi* by the rat-flea (*Ceratophyllus fasciatus*). The experiments that form the subject of this communication are concerned essentially with the *method* of transmission and with questions connected therewith. Incidentally, the *fact* of transmission is confirmed. All experiments were arranged so as to eliminate the possibility of infection other than by fleas, and to separate "direct" from "cyclical" infection. When preliminary experiments showed that infection, not "direct," had taken place, further experiments were arranged to determine if fleas once infective retain infection so as to be capable of infecting a series of healthy clean rats without themselves being again exposed to infection, and at the same time to determine by direct observation and within narrow limits (1) the length of the incubation period in the flea, and (2) the length of the multiplication period in the rat. In all the experiments tame rats and fleas bred in captivity were used. The general arrangements and a detailed account of each experiment are given, but cannot be summarised briefly. A few observations on fleas dissected are recorded, and reference is made to Nuttall's experiments and conclusions. The following conclusions are drawn from the results of the experiments:—(1) The rat-flea (*Ceratophyllus fasciatus*) transmits *T. lewisi* from infected to non-infected rats. (2) Transmission takes place by the "cyclical" method. (3) Transmission by the "direct" method did not take place. (4) The incubation period in the flea has a minimum length of about six days, but may be longer. (5) The length of the multiplication period in the rat is about twelve days. (6) In the developmental cycle the establishment of the trypanosome in the flea begins with multiplication of Crithidia-like forms in the rectum. No flagellates have been found by the authors in any fleas which had not fed on infected rats.—Dr. F. **Medigreceanu** (Bucharest): The relative sizes of the organs of rats and mice bearing malignant new growths. The effects have been determined for rats and mice of the growth of transplanted carcinomata and sarcomata upon the weights of the principal organs of the body. The weights of the different organs of normal animals bear a relatively constant ratio to the total weight of the body. Weighing experiments on 200 mice and rats bearing transplanted tumours, and on four mice with spontaneous tumours, have shown (1) no disturbance of the normal ratio for the alimentary canal; (2) hypertrophy of the liver in all cases, and up to a certain point proportional to the weight of tumour; (3) hypertrophy of the heart, also in proportion to size of tumour; (4) no disturbance of normal ratio for the kidneys except in the case of a spindle-celled sarcoma, which induced hypertrophy; (5) varying ratios for the lungs. The most important result has been the discovery of an enlargement of the liver in animals bearing carcinomata and sarcomata, whether transplanted or naturally arising.—Dr. E. F. **Bashford** and Dr. B. R. G. **Russell**: Further evidence on the homogeneity of the resistance to the implantation of malignant new growths. The principal object of the paper is to adduce further evidence that the resistance which animals already bearing transplanted tumours may offer to a second transplantation is identical in nature with the resistance offered by animals without tumours, after immunisation with normal or tumour tissue of the same species. A study of the processes at the site of the second implantation shows that, concomitantly with the establishment of the tumour developing from the first inoculation, an active resistance may be induced by the absorption of tumour tissue. Then the cancer cells implanted at the second inoculation fail to elicit the supporting connective tissue and vascular scaffolding necessary to their development into a tumour, and the process of resistance is exactly analogous to that previously described, when tumour tissue is implanted into mice after a preliminary immunisation with tumour or normal tissue of the same species. The assumption of a distinct form of resistance, "atreptic immunity," is thereby rendered superfluous when tumour-bearing animals are resistant to a second inoculation. Prevailing conceptions of what constitutes immunity to cancer *sensu strictiori* are simplified further by experiments demonstrating that the active immunity to cancer which follows in rats after a preliminary inoculation of mouse cancer is not an immunity against cancer, but against the protein of a foreign species. Therefore hypotheses of cancer immunity, based upon a study of the behaviour of tumours in strange species, have at most only an indirect bearing upon the immunity to cancer of the same species. By actual observation of the processes occurring in animals immunised against the inoculation of cancer of their own species, only one form of induced resistance has been demonstrated to exist, consisting, so far as elucidated, in an inhibition of the chemiotactic powers the cancer cells normally exercise upon the connective tissue and vascular scaffolding of the host. This single explanation harmonises all the observed facts and rids the experimental study of cancer both of confusing hypotheses and of errors.—Dr. M. **Haaland**: The contrast in the reactions to the implantation of cancer after the inoculation of living and mechanically disintegrated cells. Inoculation of living tumour of normal tissue of the same species has been shown to induce resistance to subsequent transplantation of cancer. The present paper records experiments in which cancerous or normal tissues, after mechanical disintegration at −180° or 0° C., have been inoculated into mice. The experiments show that a complete disintegration of the cells entirely robs them of their immunising properties against a subsequent transplantation of cancer. There is no difference between tumour cells and normal cells in this respect. The absence of immunising power does not seem to be a question of dose of introduced material, because relatively enormous doses of dead material do not induce any resistance. In the same way the press-fluid, obtained from tumours and normal tissues by Buchner's press, is devoid of immunising properties. The immunising property is not bound up with the protein of the cell, but depends on a different principle. Living cells are necessary to induce resistance to transplantation of cancer. It seems necessary that these cells must not only remain alive, but also even grow for a certain time; without the fulfilment of these conditions the reaction inducing active resistance is not set up. The same consequences follow autolysis, the action of heat, radium, &c., upon tumour tissue and normal tissue. The reaction which the introduction of disintegrated cells calls forth is not only quantitatively different from that induced by living tissues, but also qualitatively different. Far from inducing any increased resistance, inoculation of disintegrated cells only seems to manure the soil for a subsequent growth of tumours. The failure to elicit the reactions of immunity to the transplantation of cancer by devitalised tissues reveals an important difference from the immunity reactions obtained against bacteria and their products and foreign proteids in general, in which cases the immunising properties are independent of the vitality of the organisms or cells.

Royal Microscopical Society, January 19.—Sir E. Ray Lankester, F.R.S., president, in the chair.—The **President** gave the annual address, in the course of which he referred to such work as he thought could be carried out by the fellows with reference to the action of light upon protoplasm, the differentiation and specific effects of α, β, and γ rays emanating from radium, and the part actually played by bacteria in the processes of digestion. Medical science wanted their assistance in these investigations, which he thought could be, in some directions, better followed up by naturalists than by physiologists. Attention was also directed to an organism (*Clathrocystis aeruginosa*) found by Henfrey in 1852, in a pond in Kew Gardens, and so named by him, as worthy of their attention.

Institution of Mining and Metallurgy, January 20.—Mr. Edgar Taylor, president, in the chair.—A. L. **Simon**: Copper leaching plant in the Ural Mountains. A resumed discussion on this paper, which deals with the plant at the Gumeshevsky Copper Mine. The paper contained figures dealing with the installation and the cost of production, and a detailed description of the plant installed and the methods employed in operating it.—A. T. **French**: Some analyses of copper blast-furnace slags and determination of their melting points. The author gives tabulated results of a series of experiments, from which he deduces that slags may vary in composition to a considerable extent with very little change in the melting point.—Bede **Collingridge**: Errors due to the presence of potassium iodide in testing cyanide solutions for protective alkalinity.—A. R. **Andrews**: The detection of minute traces of gold in country rock.

Challenger Society, January 26.—Sir John Murray in the chair.—L. W. **Byrne**: A remarkable fish, apparently a new generic type, belonging to the family Stomiatidæ, taken from a trawl lowered to 700 fathoms off south-west Ireland.—James **Murray**: Life under Antarctic conditions. Sketching the difficulties of zoological research at high latitudes, the author described some unsuccessful experiments as a guide to fellow-workers. Between tide-marks no marine animals were found, the lower limit of this barren zone being the average depth of one year's ice; below that were always animals, protected by the ice, and living under singularly unvarying conditions. The land was extremely barren; the vegetation consisted of dwarfed mosses and lichens; the microscopic animals were rotifers, tardigrades, &c., which are permanently frozen through the ten months of winter, and in the summer thaw by day and freeze by night. The smaller ponds, which sometimes reached 60° F. in the summer owing to melted snow flowing over warm rocks, contained very little plankton, blue-green algæ, bacteria, and infusoria; the rotifers, &c., were found at the bottom on a plant of which nothing is known, perhaps lichenous in nature. The larger lakes were not melted through in three summers; a few animals were, however, obtained by boring. The rotifers lived under normal conditions at anything between 60° and −4° F.; they survived under experiment the temperatures of boiling water on the one hand, and on the other of a mixture of solid CO_2 and alcohol of about −172° F. While these fresh-water forms can bear such enormous temperature differences, the marine animals died if heated or cooled to a few degrees from their normal.

DUBLIN.

Royal Dublin Society, January 25.—Prof. J. A. McClelland, F.R.S., in the chair.—Prof. S. **Young**: The vapour pressures, specific volumes, heats of vaporisation, and critical constants of thirty pure substances. The determination of the vapour pressures, specific volumes, and critical constants of a number of pure liquids was commenced in 1888 in order to test the validity of the generalisations of Van der Waals regarding "corresponding" temperatures, pressures, and volumes. The data have been published at various times in several scientific journals. New or improved methods of experiment or calculation have been devised or adopted in the course of the work, and some of the data have required correction from time to time; it happens, consequently, that complete data for any one substance are not to be found in a single paper. The whole of the data, including the values obtained before 1888 by Ramsay and Young for ethyl ether, three alcohols, and acetic acid (up to 280°), have now been revised and collected, and are tabulated in this paper, which also contains a brief account of the methods of preparation and purification of the thirty liquids, and a description of the apparatus and methods employed for the determination of the physical constants. The heats of vaporisation have been calculated by Dr. J. E. Mills by means of the Clapeyron-Clausius formula, and he has very kindly supplied the data. The author is also indebted to Dr. Mills for some of the other calculated data.—Prof. J. **Wilson**: The inheritance of coat colour in horses. Having stated that Mr. C. C. Hurst had already shown (Proc. Royal Society, vol. lxxvii., 1906) chestnut to be recessive to bay and brown—the two taken as one—the author proceeded to show where some other colours fit in. Much uncertainty exists among breeders in distinguishing bay from brown, and dark brown from black. Allowing for this, the five main colours form a series in which those towards one end are recessive to all towards the other. Chestnut is recessive to black, bay, brown, and grey; black to bay, brown, and grey; bay to brown (probably) and grey; and brown to grey. The position of two other colours can be fixed only approximately, for want of sufficient data. Dun is dominant to all to the left of brown, that is, to chestnut, black, bay, and brown. Roan is also dominant to chestnut, black, bay, and brown, and perhaps also to dun and grey; but it has this peculiarity, that the roan does not blot out the other colours, but the white hairs of the roan mingle with coats of the other colours. This implies that there are chestnut roans, bay roans, and so on.

PARIS.

Academy of Sciences, January 24.—M. Émile Picard in the chair.—Ch. **André**: The Johannesburg comet. This was seen by M. Guillaume on January 21. It was very brilliant, its nucleus having a brightness a little greater than that of Arcturus.—Alfred **Grandidier**: The international map of the earth on the scale of 1/1,000,000. At the Geographical Congress held at Vienna in 1891 Prof. Penck suggested the production of a uniform map of the earth on the scale of 1 in 1,000,000, and an account is given in the present paper of the progress that has been made with this map, and the difficulties owing to lack of uniformity in the conventional signs employed. The total cost of this work is estimated at 5,000,000 francs.—E. **Esclangon**: Observation of Drake's comet. A description of the appearance of the Johannesburg comet on January 22 at Bordeaux.—H. **Bourget**: Observations of Drake's comet (1910*a*) made at the Observatory of Marseilles. Positions of the comet are given for January 19, 20, and 21.—Remarks by M. **Baillaud** on this paper, giving an account of other dates and places in France where observations of the comet had been made.—E. **Maubant**: The elements of Tempel's comet.—J. **Le Roux**: The conditions of maximum or minimum of an analytical function with an infinity of variables.—D. **Mirimanoff**: The last theorem of Fermat.—M. **Galbrun**: The representation of the solutions of a linear equation of finite differences for large values of the variable.—Paul **Helbronner**: The connections of the meridian chain of Savoy with the fundamental Italian and Swiss triangulation.—Edm. **van Aubel**: Pulfrich's relation between the volume contraction and the refractive power of mixed liquids. A discussion of the experimental data of R. Wintgen on the density and refractive indices of solutions of salts and acids from the point of view of the formula of Pulfrich.—P. **Vaillant**: The laws of evaporation. In the apparatus devised by the author the quantity of liquid evaporated per second is independent of the nature of the liquid, depending only on the area of the opening through which the vapour of the liquid escapes. An examination of numerous liquids led to the relation $q=a\mathrm{MF}^{\frac{4}{3}}$, in which q is the rate of evaporation per second, F the maximum vapour pressures of the liquids at the temperature of the experiments (20° C.), and a an approximate constant. To fall into line with the other liquids, it is necessary to attribute the molecular weight $(H_2O)_3$ to water.—C. **Féry**: Prisms with curved faces applicable to spectroscopy. The object of the arrangement described and figured is to reduce the spectroscope to the slit, prism and ocular, or photographic plate. The arrangement possesses advantages in stellar spectroscopy.—Gaston **Gaillard**: Observation of a dissymmetry in the velocity of solution of crystals of sugar along the different faces.—J. **Chaudier** and Ed. **Chauvenet**: The radio-activity of the halogen and oxyhalogen compounds of thorium. The radio-activity of these compounds of thorium for quantities of substance containing more than 10 milligrams of thorium varies with the nature of the associated elements. The intensity of the radiation diminishes as the atomic weight of these elements increases. The curves of radio-activity of the various compounds of thorium tend towards that of thorium as the quantities of material are reduced.—Pierre **Camboulives**: The action of carbon tetrachloride vapours upon some minerals. Many natural oxides are attacked by the vapours of carbon tetrachloride as easily as the oxides prepared in the laboratory. Corundum offers an exception, being attacked only to the extent of 11 or 12 per cent., whilst alumina arising from the calcination of ammonia alum is completely transformed. Wolfram is so readily acted upon that the process forms the basis of a good analytical method. Silicates are the more readily acted upon the poorer they are in silica. Numerous examples are given.—F. **Kerforne**: An auriferous lode situated at Beslé (Loire-Inférieure). An account of some ancient gold workings.—Ch. **Moureu** and J. Ch. **Bongrand**: Carbon subnitride, C_4N_2. This substance, which is the second definite compound known of carbon and nitrogen, is formed by the removal of water from butine diamide, $NH_2—CO—C\equiv C—CO—NH_2$, and hence has the constitution $N\equiv C—C\equiv C—C\equiv N$, or dicyanacetylene. It forms fine white needles, melting at 21° C. and boiling at 76° C. under a pressure of 753 mm. Its vapour is violently irritating, and catches fire in the air at a temperature of about 130° C. Particulars are given of the analysis, determination of the vapour density and molecular refraction, and further work is being carried out on its physical and chemical properties.—Maurice **Lombard**: The chemical and biological effects of the ultraviolet rays. The formation of nitrites in these experiments is definitely proved.—Gabriel **Bertrand** and M. **Holderer**: New observations on the individuality of cellase. Details of experiments proving that cellase is a specific diastase. It is found, more or less mixed with other species of diastases, in barley, almonds, the mycelium of *Aspergillus niger*, &c.—M. **Marage**: The photography of the voice in practical medicine. The photography of the vibrations of the larynx shows very clearly the state of the voice at the beginning and end of a course of treatment. Its use as an aid to diagnosis is being further examined.—A. **Rosenstiehl**: The consequences of Young's hypothesis. The sensation of binary white.—P. **Hachet-Souplet**: The association of sensations in animals. The law of recurrence.—A. **Lécaillon**: The structure and signification of the membrane which envelops the vitelline sphere in the egg of birds.—Léon W. **Collet**: The presence of fossil-bearing Cenomanian in the limestone Alps of Haute Savoie.—E. **de Martonne**: The genesis of Alpine glacial forms.—Kr. **Birkeland**: The magnetic deviability of the corpuscular radiations proceeding from the sun.—Alfred **Angot**: The earthquake of January 22, 1910. The seismograph of the Parc Saint-Maur Observatory recorded a distant earthquake of great violence on January 22. The examination of the seismograms showed that the epicentre was about 3000 kilometres to the south-east. Observations from other stations are required to fix the direction with certainty.—Bernard **Brunhes**: The record of an earthquake on January 22, 1910, at the Puy de Dôme Observatory. The seismograms indicated 3000 to 3500 kilometres as the distance of the epicentre.

January 31.—M. Emile Picard in the chair.—H. **Deslandres,** A. **Bernard,** and L. **d'Azambuja**: First observations of Drake's comet at the Observatory of Meudon. Spectroscopic observations were possible on January 22, 24, 25, 27, 29, and 30. Changes in the comet's spectrum were observed during these days. At first the sodium line was the most marked, together with a faint hydrocarbon band. The strength of the sodium line diminished from day to day, the hydrocarbon bands increasing in clearness and the bands of cyanogen appearing. On the last two days the sodium line became invisible, but the spectra of the hydrocarbons and cyanogen became complete and intense. The spectrum of the hydrocarbons even appeared to extend a considerable distance into the tail. These changes are exactly those undergone by the large comet of 1882.—B. **Baillaud**: The photographic map of the sky. Presentation of the proceedings of the last congress.—A. **Muntz**: The mud carried away by the waters of the Seine. Determination of the amount of mud in suspension in the Seine shows that the total amount carried away by the river between January 25 and 29 varied from 18,800 to 11,000 tons per day. This is not regarded as causing a serious loss of fertility in the soil from which this mud has been removed.—Edmond **Perrin** gave an account of the state of the museum after the floods.—Henri **Douville**: The discovery of the marine Trias at Madagascar.—M. **Giacobini**: Observations of the comet 1910*a* made at the Observatory of Paris with the 38-cm. equatorial. Positions are given for January 22, 24, 25, 27, 29, and 30.—P. **Chofardet**: Observations of the Johannesburg comet, 1910*a*, made at the Observatory of Besançon with the bent equatorial. Positions given for January 27 and 29.—Ch. **Lallemand**: A systematic error in the determination of the mean level of the sea by the medimaremeter. In this instrument, consisting of a tube closed at the lower end by a porous pot, the water-level oscillates round the mean sea-level. The systematic error now discovered is due to the removal of a few drops of water each time a tube is introduced to take the level. On this account the readings of the instrument are 1·5 mm. too low.—M. **Biquard**: A method of measuring the coefficient of thermal conductivity of badly conducting bodies. In the instrument described the heat is transmitted regularly through isothermal surfaces, the amount being measured by the rate of production of water from ice.—G. **Thovert**: Diffusion and the kinetic theory of solutions. An extension of the method previously described to solutions in methyl alcohol.—Ch. **Fabry**: The intrinsic brightness of the starry sky.—J. H. **Russenberger**: The absorption of liquids by porous substances.—F. **Laporte** and P. **de la Gorce**: Researches on the electrochemical equivalent of silver carried out at the Central Electrical Laboratory. Successive improvements introduced into the purification of the silver nitrate used in these experiments have resulted in the removal of the difference of 0·0004 originally found between the determinations of the National Physical Laboratory and those made at the Central Laboratory in Paris. The general mean of the results is 1·11829 mgr. silver per coulomb.—G. **Fouquet**: The spontaneous crystallisation of sugar.—M. **Oberreit**: The synthesis of 5 : 7 : 5′ : 7′-tetrachlorindigo.—[illegible] **Yvon**: Aniline emetic. This is prepared by the inter[illegible]ion of oxide of antimony and the acid tartrate of [illegible] Figures are given for its density, rotatory power, [illegible]bility, and crystalline form.—Maurice **Holderer**: The influence of the reaction of the medium on the filtration of some malt diastases.—H. **Agulhon**: The use of boron as a catalytic manure. From the experiments described it is concluded that boron is an element of use to the higher plants. The addition of a small quantity of boron (in the form of boric acid) to a culture medium or to a natural soil leads to a sensible increase in the weight of dry material formed.—André **Brochet**: The radio-activity of some springs in the Vosges.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 10.

ROYAL SOCIETY, at 4.30.—Some Phenomena of Magnetic Disturbances at Kew: Dr. C. Chree, F.R.S.—On a Novel Phenomenon in the Diurnal Inequality of Terrestrial Magnetism at Certain Stations: R. B. Sangster.—The Absorption Spectra of Vapours of the Alkali Metals: Prof. P. V. Bevan.—On the Shapes of the Isogeotherms under Mountain Ranges in Radio-active Districts: Prof. C. H. Lees, F.R.S.—On the Propagation of a Disturbance in a Fluid under Gravity: F. B. Pidduck.—On the Flow of Water through Pipes and Passages having Converging or Diverging Boundaries: Dr. A. H. Gibson.—The Effect of Pressure upon Arc Spectra: Titanium: R. Rossi.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Losses off Transmission Lines due to Brush Discharge, with Special Reference to the Case of Direct Currents: E. A. Watson.

MATHEMATICAL SOCIETY, at 5.30.—A Note on Double-sixers of Lines: H. W. Richmond.—On the Diffraction of a Solitary Wave: Prof. H. Lamb.—Notes on Various Points in the Theory of Functions: Dr. H. F. Baker.

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Waves in Water, Sand, and Snow: Dr. Vaughan Cornish.

FRIDAY, FEBRUARY 11.

ROYAL INSTITUTION, at 9.—Electrical and other Properties of Sand: C. E. S. Phillips.

PHYSICAL SOCIETY, at 8.—Annual General Meeting. President's Address.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Anniversary Meeting.

MALACOLOGICAL SOCIETY, at 8.—Unio, Margaritana, Pseudanodonta, and their Occurrence in the Thames Valley: Fritz Haas.—(1) Pleistocene, Holocene, and recent Non-marine Mollusca from Mallorca; (2) Marine Mollusca from Alcudia, Mallorca: Rev. R. Ashington Bullen.—Description of a New Species of Vivipara from New Guinea: H. B. Preston.—Description of a New Species of Unio from the English Wealden Formation: R. Bullen Newton.

SATURDAY, FEBRUARY 12.

ROYAL INSTITUTION, at 3.—Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

MONDAY, FEBRUARY 14.

ROYAL SOCIETY OF ARTS, at 8.—The Petrol Motor: Prof. W. Watson, F.R.S.

TUESDAY, FEBRUARY 15.

ROYAL INSTITUTION, at 3.—The Emotions and their Expression: Prof. F. W. Mott, F.R.S.

ILLUMINATING ENGINEERING SOCIETY, at 8.—Glare, its Causes and Effects: Dr. J. H. Parsons.

ZOOLOGICAL SOCIETY, at 8.30.—Kinematograph Demonstration (Studies in the Society's Gardens): Charles Urban.—Additions to our Knowledge of the Fossorial Wasps of Australia: R. E. Turner.—Descriptions of New Lycænidæ and Hesperiidæ from Tropical West Africa: H. H. Druce.—On certain Subcutaneous Fat-bodies in Toads of the Genus Bufo: C. L. Boulenger.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further discussion*: Notes on the Sheffield Water-supply and Statistics relating thereto: L. S. M. Marsh.—Statistical and Experimental Data on Filtration: W. R. Baldwin-Wiseman.

ROYAL STATISTICAL SOCIETY, at 5.

WEDNESDAY, FEBRUARY 16.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Notes on *Dendrobrachia fallax*, Brook, a Rare and Divergent Antipatharian: Prof. J. Arthur Thomson.—(1) On the Measurement of the First Nine Groups of Grayson's Finest Twelve-band Plate; (2) On the Measurement of the Diameter of the Flagella of the Cholera Bacillus prepared by Löffler's Method: A. A. C. Eliot Merlin.

ROYAL SOCIETY OF ARTS, at 8.—The Lifeboat and its Work: Sir John C. Lamb, C.B., C.M.G.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Report on the Phenological Observations for 1909: E. Mawley.—The North Atlantic Anticyclone. Tracks of the Centres of High Areas 1882–3: Colonel H. E. Rawson, C.B.

THURSDAY, FEBRUARY 17.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Phosphorescence produced by α and β Rays: E. Marsden.—Theory of the Luminosity produced in Certain Substances by α Rays: Prof. E. Rutherford, F.R.S.—(1) The Scattering of the α Particles by Matter; (2) The Ionisation produced by an α Particle. Part II.: Connection between Ionisation and Absorption: Dr. H. Geiger.—The Influence of Pressure on the Boiling Points of Metals: H. C. Greenwood.—On the Viscosities of the Gases of the Argon Group: A. O. Rankine.

ROYAL INSTITUTION, at 3.—Illumination, Natural and Artificial (Experimentally Illustrated): Prof. S. P. Thompson, F.R.S.

LINNEAN SOCIETY, at 8.—The Plum-moths of the Seychelles Expedition: T. B. Fletcher, R.N.—Die von Herrn Hugh Scott, auf den Seychellen gesammelten Embiidinen, Coniopterygiden und Hemerobiideen: Dr. G. Enderlein.—Die Termiten der Seychellen-Region: Dr. Nils Hohngreen.—On the Land and Amphibious Decapoda of Aldabra: L. A. Borradaile.

ROYAL SOCIETY OF ARTS, at 4.30.—The Bombay Housing Question: G. O. W. Dunn.

INSTITUTION OF MINING AND METALLURGY, at 8.

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Waves in Water, Sand, and Snow: Dr. Vaughan Cornish.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 5.—Head Hunters in Assam: T. C. Hodson.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electric Clocks: F. Hope-Jones.

FRIDAY, FEBRUARY 18.

ROYAL INSTITUTION, at 9.—Halley's Comet: Prof. H. H. Turner, F.R.S.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Annual General Meeting.—*Further discussion*: Ninth Report to the Alloys Research Committee: On the Properties of some Alloys of Copper, Aluminium, and Manganese (with an Appendix on the Corrosion of Alloys of Copper and Aluminium when Exposed to the Sea): Dr. W. Rosenhain and F. C. A. H. Lantsberry.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Irrigation Works: Sir R. Hanbury Brown, K.C.M.G.

SATURDAY, FEBRUARY 19.

ROYAL INSTITUTION, at 3.—Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

ASEPTIC SURGERY.

The Collected Papers of Joseph, Baron Lister. Two vols. Vol. i., pp. xliv+429; vol. ii., pp. vii+589. (Oxford: Clarendon Press, 1909.) Price 2*l.* 2*s.* net.

ALTHOUGH the numerous papers collected in these two volumes were for the most part written thirty or forty years ago, their interest is in no way diminished to-day. Had the work of Lister failed to meet with due appreciation, his friends and pupils could have found no surer way of obtaining this than by the simple collection of his writings into these two volumes, and when one has said "this was his work," no further comment or eulogium is possible. In the records of most epoch-making discoveries one can read between the lines the character of the discoverer. At first sight it would seem as if the papers dealt with many and diverse subjects, but more careful study shows a remarkable unity, each one constituting a step towards the great work with which the name of Lister will always be associated.

With the exception of one or two isolated physiological papers, Lister's work was directed towards the elucidation of the meaning of the phenomena, which followed injuries to living organisms, commonly summed up under the term inflammation. Lister carried out a long series of experiments on the coagulation of blood, which must ever remain as a pattern of carefully planned and skilfully worked out investigation; and it was the relationship between inflammation and vascular thrombosis which determined the point from which he attacked this problem.

Lister's observations had for their object the study of blood coagulation in the vessels themselves, and he attempted to discover why blood which coagulated so readily when shed into a basin remained fluid in contact with living or surviving tissues. His experiments upon inflamed blood-vessels, conducted largely upon the web of a frog's foot, in spite of the large amount of work which has been done on this subject, require but little revision; his experiments on the pigmentary corpuscles in the frog form one of the most brilliant demonstrations of the effect of injury on the tissue cells as distinguished from changes in the blood-vessels.

Naturally, however, the greatest interest of Lister's work centres around the papers on the use of antiseptics. Surgery was not merely revolutionised—a new science was born. His article on "A New Method of Treating Compound Fracture, Abscess, &c., with Observations on the Conditions of Suppuration," gave the result of two years' experience in the new methods. This paper was published in 1867, and reading it to-day it is difficult to conceive why theories so ably argued and so conclusively proved failed to obtain immediate acceptance; but for many years Lister shared the common fate of reformers, and had to cope with misunderstanding and misrepresentation. It is appalling to think that in the great war of 1870 and 1871 no real attempt was made to use the methods which Lister had employed for four years. The opposition, however, to Lister's methods was not unique, for in the article on anæsthetics in these volumes, written in 1861, seventeen years after the discovery of ether, Lister remarks

> "that such being the great benefits conferred by this agent it is melancholy to reflect that in many parts of Europe and even of the United Kingdom it is either withheld altogether or given so scantily as to be nearly useless."

The "sepsis" which Lister was attacking was not the sepsis which is known to-day, but actual putrefaction of the discharges from wounds, to which were attributed the septicæmia, pyæmia, and hospital gangrene which were so prevalent before the antiseptic era. It is hard to-day to think of being familiar with

> "the faint sickly smell commonly perceptible in surgical wards under ordinary treatment, and still more with the stench which prevails at the time of the daily dressing";

but at that time it was a matter of common experience. The value of the antiseptic method could not have been more severely tested than in the original men's accident ward in Glasgow Infirmary, in which it was first put in practice. Separated from this ward by a passage 12 feet wide was another similar ward, in which the death-rate from pyæmia and hospital gangrene was so high that it attracted the attention of the authorities even at this time. An excavation was made, and it was found that on a level with the floors of these two wards, with only the basement area, 4 feet wide, intervening, was the uppermost tier of a vast number of coffins, placed there during the cholera epidemic of 1849. In addition to this, one end of the surgical hospital abutted on the cathedral burial yard, in which the revolting practice of pit burial was carried out; that is to say, bodies of paupers enclosed in rough coffins were placed in large pits, which were loosely covered up with boards, and only filled in with earth when the pit was full. In such circumstances as these, Lister was able to state, at the British Medical Association meeting in Dublin, that for the nine months in which the antiseptic system had been in proper working order not a single case of pyæmia, erysipelas, or hospital gangrene had occurred in his ward, although these diseases were exceptionally rife in the other wards of the hospital.

In the first attempts at antiseptic surgery, German creosote, a crude form of carbolic acid, was introduced into the wound on a strip of lint, which was in some cases left in position; some fresh antiseptic was mixed with the blood exuding from the wound so as to form a crust, the carbolic acid in which was then prevented from evaporating by a piece of block tin; this was removed once or twice a day, and fresh carbolic acid painted on the crust to supply the place of that which had evaporated. Crude and irritating as this method was, its results were an enormous improvement on any that had been previously obtained. Of the first eleven cases of compound fracture and dislocation treated in this way only one died, although at this time recoveries were extremely rare, and the accident was regarded as one of the most dangerous known to surgeons.

Carbolic acid was first brought to Lister's notice by reading accounts of its deodorising action upon the sewage of Carlisle, and it is interesting to note that this, the first substance used by Lister in his antiseptic method, still retains its pre-eminence as an all-round antiseptic.

These first methods were only a beginning, and throughout the whole course of his active life Lister busied himself in perfecting his method, striving to find means whereby asepsis could be secured with a minimum irritation of tissues, without deviating in the slightest degree from those scientific principles which had guided him at the outset of his work.

The conquest of suppuration not only perfected older operations, but opened the way for new ones, and Lister himself introduced a large number of these. Joints, interference with which had been looked upon as utterly unjustifiable, were opened with impunity, fractures with vicious union were exposed and rectified, new principles in amputation introduced, and the use of the aseptic ligature, by obviating the risks of hæmorrhage, removed one of the greatest dangers of surgery.

Not the least interesting of the papers collected in these volumes is that on anæsthetics, a subject to which Lister devoted a considerable amount of attention, and in view of the recently proposed legislation it is interesting to note that Lister strongly disapproved of specialists in this branch of practice, holding that the administration of an anæsthetic called for care rather than for special skill and experience.

Lister in all his writings frankly and gratefully acknowledged and appreciated the work of others, especially Pasteur, and that "hard-worked general practitioner," Koch. His work is its own monument; it has given modern surgery to mankind, and so simplified its performance that operations can be performed without any particular comment which fifty years ago would have left the whole world aghast at their daring.

A NATURALIST IN ECUADOR.

Nel Darien e nell' Ecuador. Diario di viaggio di un Naturalista. By Dr. E. Festa. Pp. xvi+397. (Torino: Unione Tip.-Editrice Torinese, 1909.) Price 10 lire.

DR. E. FESTA'S main object was the zoological exploration of Ecuador. However, as the isthmus of Darien or Panama lies on the way to Ecuador, and since this interesting country happened to pass through one of its revolutions, he spent the time from the months of May to September, 1895, on the isthmus, chiefly among the intricate inlets of the Gulf of San Miguel, on the Pacific side, extending thereby his collecting over every class of the animal kingdom, from sponges to mammals.

After the political conditions had become a little more settled, he went to Ecuador in September, 1895, and stayed there to April, 1898. Entering the country by Guayaquil, he travelled east to Cuenca and beyond, to the headwaters of the Rio Santiago of the Marañon system, and northwards by Quito to Julian, near the frontier of Colombia. His travels, extending, roughly speaking, from 4° latitude south to 1° north, and between 80° to 78° longitude west, cover only a small part of the vast country of Ecuador, but he explored it thoroughly.

He was much indebted to the President of the Republic; for instance, on the strength of his official credentials the local authorities occasionally commandeered porters and mules. Above all, he was helped by the missions of the Società Salesiana de Torino, and he had the inestimable advantage of being accompanied on his perilous excursions through the forests of the Santiago district by a former compatriot, Sr. G. Pancheri. An agreeable feature was the hospitality offered by many Ecuadorean owners of haziendas. About 500 specimens of mammals, more than 3000 birds, 150 different kinds of reptiles and amphibians, as many kinds of fishes, and ever so many invertebrates, were brought together and given to the Royal Museum at Turin. They testify to the richness of the fauna, and last, not least, to the enormous labours of Dr. Festa and the Italian collector whom he was able to take with him. However, they took whatever kind they could, and of every kind as many specimens as possible. For instance, no fewer than nine condors were shot at one spot, and in typically national style the travellers spread nets in forest and garden, and gloated over the numbers of little beauties ensnared. The step thence to that pest, the plume-hunter, seems but small; at least, it is a bad example to the natives.

Naturally our author experienced many ups and downs, but he had no hairbreadth escapes, as such are now of rare occurrence to veracious travellers. Already in the mangrove swamps of Darien he suffered much from fever and severe gastric troubles, and camp life was often utterly spoiled by the pests of insects. It was not only the stinging, poisonous kinds, but a great aggravation were the stingless bees, Melipone, big and small, which in their numbers insinuated themselves into the hair, mouth, nose, and ears. To make work possible, the traveller had to put smouldering branches upon the table. Some kind of Oestrus stung Dr. Festa in the abdomen, causing several months of torment, and after opening the swelling he extracted a fat maggot, four centimetres in length. The horses suffered indirectly from the bites of the blood-sucking bats, Desmodus, because flies deposited their eggs in the little wounds, and the maggots caused enormous ulcers. Sand-fleas, *Sarcopsylla penetrans*, were a plague in many places, and every specimen of digging rodents had its feet infested with them.

Several specimens of the Andine bear, *Tremarctos ornatus*, were procured. This creature, preferring to travel in comfort, prepares its bed on the ground, by covering a space about a yard in diameter with branches and twigs to lie upon during the night.

After having found such "beds," the travellers came across a family of bears, which had their lair at the foot of a tree, hidden by dense foliage. When dislodged, some of them climbed about rapidly.

The beautiful Morpho butterflies were abundant at places, and not at all shy. On the contrary, they alighted upon the table and sucked from the dishes during breakfast. At Cuenca Dr. Festa was treated to the spectacle of a fierce battle, which lasted all day long, and on the following day the victor entered the town after a loss of 900 dead. A rather full and interesting account is given of the Iivaros tribe of Indians, who, not yet appreciating the value of money, required knives, guns, needle and thread, &c., for barter. The wilder they were, the better they were as collectors. Their special weapon is the blowpipe. A favourite ornament of both sexes, besides painting themselves, is a wooden lip-plug, one inch long and half an inch thick, with pendants of needles, the brightly-coloured wings of beetles, &c. The house is large, of the type of the communal house, the sexes occupying different quarters of the same large room, and to each woman's bed are tied several fierce watchdogs.

In the mountains of the province of Carchi were procured a considerable number of antique specimens of pottery and some crania.

Unfortunately, this book is written mostly in the style of a diary, which does not well lend itself to generalisations, but rather to matter-of-fact records of animals and plants observed. It would have been interesting to read how the Ecuadorean civilisation appeared to an Italian, a cultured representative of another Latin race. The English-speaking civilisation is too divergent from the Latin-American in almost every walk of life really to understand it and to appreciate its many good points. However, the author is modest, and enlivens his account of the many things he has done and seen with but little humour.

The book, printed in excellent type and on very good paper, and adorned with some seventy or eighty, mostly full-paged, beautifully reproduced photographs, seems wonderfully cheap for the price of 8*s.*

AUSTRALIAN ANIMALS.

The Animals of Australia. Mammals, Reptiles, and Amphibians. By A. H. S. Lucas and W. H. Dudley le Souëf. Pp. xi+327. (Melbourne: Whitcombe and Tombs, Ltd., 1909.) Price 15*s.* net.

MESSRS. LUCAS AND LE SOUËF have given us a book which ought to find a very hearty welcome, especially amongst Australian naturalists. Whilst intended primarily for the general reader, the arrangement and treatment are throughout thoroughly scientific, and the illustrations, many of which are from original photographs, are, on the whole, very good. The full-page photograph of a wheelbarrow on p. 179 is perhaps a little superfluous, however. It is true that the wheelbarrow contains a snake, but it is a very small one, and a much better photograph of the same snake is given on another page.

The information that the number of Australian species of Eutheria is the same as that of the marsupials (106) comes rather as a surprise, even if, as we suppose, it includes introduced species.

The authors have a melancholy tale to tell of the rate at which the marsupials are being exterminated for the sake of their skins. It appears that no fewer than 873,837 "opossum" skins were offered for sale in the Sydney market alone during the year 1908, and other species in hardly less alarming numbers.

The section dealing with the snakes is one of the most interesting. Death from snake-bite appears to be rare in Australia, although many of the species are poisonous, and some of them deadly. In case of snake-bite, however, most people prefer to err on the safe side, though there are probably not many who have so much to show for their mistake as the man who exhibits to his friends a bottle containing one of his own fingers and a perfectly harmless snake by which it had been bitten! Snake-stories form an important part of the literature of the Australian bush, but we do not recollect having heard before about the tiger-snake which was found enjoying a sun-bath balanced on the topmost wire of a fence, with the folds of the body nicely adjusted on each side to maintain the balance. We are told that the Australian snakes do not charm or fascinate their prey in any way (p. 156). If this is so, we are at a loss to understand the photograph on p. 181, which, at first sight, at any rate, looks like a snake fascinating a hen; perhaps, however, the hen is refusing to be fascinated.

One difficulty which has to be overcome by the writer of a popular book on natural history in a "new" country is the absence of a popular terminology. To some extent Messrs. Lucas and le Souëf have endeavoured to supply this deficiency; notably in the case of the Agamid lizards, for which they suggest the name "Dragons." Thus *Amphibolurus maculatus* is to be known as the "Military Dragon," presumably on account of its brilliant colours; but we should hardly have thought that "Queen Adelaide's Dragon" was an appropriate rendering of *Amphibolurus adelaidensis*, the termination of the specific name suggesting a geographical rather than a personal reference. In a few cases the Australian public has already taken the matter of nomenclature into its own hands, as in the well-known case of "Goana," which is, of course, a corruption of "Iguana," a name popularly but erroneously applied to the "lace monitor" (*Varanus varius*).

Although the book does not profess to deal with the fishes, the authors have not been able to resist the temptation to include an account of Ceratodus, evidently on the ground that it is "part fish, part amphibian." The amphibian part seems hardly sufficient to justify its inclusion, but we must admit that the temptation was very strong.

The book is well got up, though the paper is unpleasantly glossy. We can strongly recommend it to all who are interested in Australian natural history.

MACHINE DESIGN.

Elements of Machine Design. By Dr. S. Kimball and J. H. Barr. Pp. viii+446. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 12*s.* 6*d.* net.

THIS is an important work on a subject which it is difficult to treat in systematic manner on account of the great complexity of the conditions involved. The variety of machines now made is almost overwhelming, and is continually increasing, while for the successful and intelligent design of machines of any one class the engineer must possess a faculty of invention, a sound judgment, some acquaintance with commercial conditions, familiarity with workshop processes, a knowledge of the many branches of applied mechanics and of physics, all the result of long study and practical experience. The treatment of so extensive a subject must of necessity be only partial, and the primary appeal of this book is to students of technical colleges. At the same time, the expert draughtsman will find much of interest and profit. The drawings are subordinate, and are introduced mainly to illustrate principles. The treatment is logical yet practical, very suggestive and germane to the subject, and the style is attractive and interesting. The writers can speak with authority, each having had experience as a professor of Sibley College, Cornell University, and also as a manager of an engineering works.

The authors begin with some examples illustrating the energy changes which take place in a machine during a cycle of operations, the object of the investigation being to determine the maximum value and range of the force actions which occur. Then follows an explanation of how the parts are to be designed so as to withstand successfully these straining actions, and a very complete and well-arranged collection of formulæ for the strength and stiffness of beams, shafts, struts, &c., is given. The discussion of the considerations which affect the choice of a suitable factor of safety will here be found very helpful.

The chapter on friction, lubrication, and efficiency is extremely interesting and suggestive. The investigations on lubrication by Beauchamp Tower and later experimentalists are quoted and analysed, and their significance explained. Subsequent chapters are devoted to machine details, comprising springs, riveted joints, screws and bolts, keys and cotters, tubes and pipes, constraining surfaces for sliding and turning motions, shafting and couplings, belt, rope, and chain transmission, friction wheels and brakes, spur, bevel and screw gears, flywheels, pulleys and rotating discs, and, lastly, machine frames.

The chapter on constraining surfaces is one of the best in the book. Some of its drawings exhibit modern types of cylindrical and thrust bearings, and ball and roller bearings. In the general discussion the authors enter fully into the permissible bearing pressures, the details for securing efficient lubrication, the dissipation of heat from the bearing, and all the conditions for successful design. Indeed, every chapter is suggestive and interesting, but enough has been said to indicate the general character and scope of the work. We must, however, not overlook the numerical examples which are introduced at intervals, and used to illustrate and suggest the proper treatment of problems in design. Mention should also be made of the many references to publications, to assist readers who desire further information.

Altogether, the authors are to be congratulated on the production of a very instructive, well-arranged, and well-written treatise on the elements and principles of machine design. The book should be in the library of every engineering school and college.

THE ATRIUM OF SOUTH AFRICA.

An Introduction to the Geology of Cape Colony. By Dr. A. W. Rogers and A. L. Du Toit. Second Edition. Pp. xiv+492. (London: Longmans, Green and Co., 1909.) Price 9*s.* net.

THIS handbook is the second edition of that reviewed in 1905, and the progress made since then in South African geology renders its appearance all the more welcome. Dr. Rogers has associated his colleague, Mr. Du Toit, in the authorship, and the preparation of the new material has no doubt raised pleasant memories of many a long campaign, in lands where the horizon always seems to call one further, until the rim of the world sweeps up against the sunset, and another night is spent beneath the stars.

The complete revision of the work makes it virtually a new one for purposes of reference; and the coloured map is now on a larger scale, and covers additional ground, notably in Griqualand West. Two sections illustrate the folded margins of the colony, and the broad synclinal of the Karroo system, which in places measures 450 miles from side to side. The correlation of the pre-Devonian rocks (p. 5) is considered in some detail, and reasons are given (p. 110) for the retention in this group of the "continental" Matsap system on the fringe of the Kalahari. The Karroo system, from the Lower Dwyka beds to the volcanic capping of the Drakensbergen, is compared (p. 233) with South American and European strata, on the basis of recent literature. The glacial Dwyka beds, composed of the so-called "tillite," may be Upper Carboniferous or Lower Permian; but the reptilian fauna places the Upper Dwyka series in the Permian. The Beaufort beds, with Pareiasaurus, Oudenodon, and the freshwater molluscs Palæomutela and Palæanodonta, are paralleled by the Russian Permian. The Upper Beaufort or Burghersdorp series is, however, probably Triassic; so also are the succeeding Molteno beds, regarded as equivalents of the Rhætic. The Stormberg series, if we except the Molteno beds, is held to be Jurassic. Dr. Broom has entirely re-written his chapter on the Karroo reptiles, and points out that Tritylodon, which he has elsewhere shown to be most probably a Jurassic form, may be retained among the mammals.

The chapter on the volcanic pipes younger than the volcanic Stormberg series has been expanded, but no longer contains the sections of the rock-shafts at Kimberley. The relationship of their igneous infilling, known as kimberlite, to melilite-basalt (p. 364) is emphasised by new evidence from North America, in addition to that known from Cape Colony. A brilliant suggestion of Carvill Lewis becomes thus fully justified.

In the fine chapter on the geological history of the colony, the influence of Prof. W. M. Davis (p. 451) now becomes justly manifest. There was little to modify, however, in Dr. Rogers's original review of the great processes that have made South Africa. His suggestion that the S-bends of the rocky gorges in the south are the descendants of meanders formed when the rivers ran over a great plain remains happily unaltered. If South African geologists have learnt willingly from friends whom they invited in 1905 to the coast-ranges and the veld, it will be long before those friends can repay what they themselves received. The guidance then given by Dr. Rogers is renewed and extended in the present admirable volume.

G. A. J. C.

OUR BOOK SHELF.

The Romance of Modern Chemistry. By Dr. J. C. Philip. Pp. 348. (London: Seeley and Co., Ltd., 1910.) Price 5*s*.

ACCORDING to its subtitle, this book is "a description in non-technical language of the diverse and wonderful ways in which chemical forces are at work, and of their manifold application in modern life." After some prefatory historical and theoretical matter, the reader is provided with a wealth of brightly-written and interesting information about fuel and its uses, explosives, low-temperature and high-temperature appliances, and spectroscopy. Modern phases of agricultural chemistry and of industries relating to sugar, starch, fats, and oils are discussed, and the concluding chapters give well-chosen illustrations of applied chemical science in relation to the adulteration of food, the utilisation of by-products, coal-tar products, large-scale electrolysis, solutions, crystals, and industrial catalysis. The last chapter illustrates vividly the part that "accident" has played in chemical discovery.

The most formidable difficulty in writing a book of this kind is to get the reader sufficiently acquainted with the elements of chemical fact and reasoning to enable him to understand the applications. Dr. Philip has adopted a light treatment and allowed himself a free use of imagery of an anthropomorphic kind, which will probably make an impression. To a reader who knows just a little chemistry the interest from the beginning of chapter vi. to the end of the book (chapter xxx.) will be kept fully alive, and as the body of information contained in these chapters is just that which is apt to be omitted from school or evening-class courses of formal chemistry, the book has a very distinct place of usefulness. It is written with an unimpeachable knowledge of scientific chemistry, a very unacademic appreciation and knowledge of practical problems, and a certain amount of human nature, which make the best possible equipment for the author of a book intended to popularise science. The chapter on solutions is particularly worthy of mention as an example of admirable exposition. There are twenty-nine excellent illustrations, which have been selected with care and at considerable trouble, but a long accumulating detestation of the very names stalactite and stalagmite would have reconciled the present writer to a suppression of the three plates dealing with these bedridden natural and etymological phenomena.

A. S.

Hayward's Botanist's Pocket-book. 13th edition, revised and enlarged. By G. C. Druce. Pp. xliv+280. (London: George Bell and Sons, 1909.) Price 4*s*. 6*d*. net.

THE "Botanist's Pocket-book" is well known as a handy companion of a convenient size for the pocket, and containing sufficient data to determine ordinary plants in the field. The original work, published in 1872, was enlarged in 1886 by the addition of an appendix, but, as many changes have recently been rendered necessary, the publishers have wisely authorised Mr. G. C. Druce to make a thorough revision. The general plan remains the same, but there is evidence of Mr. Druce's emendations from the first page to the last. Notably, the synopsis of the natural orders has been corrected, the arrangement of the genera has been altered, and both genera and species have been carefully revised to incorporate the conclusions of present-day authorities and present the nomenclature in accordance with the recommendations of the Vienna Congress.

The revision gives all species and varieties, even certain hybrids, except for the genera Hieracium, Euphrasia, and Rubus. Although the identification of many critical species and varieties will not be decided in the field or even on the scanty data supplied, botanists will not cavil at the decision to include them, especially as it has not necessitated an increase in the size of the volume. It is not apparent why the family names Lamiaceæ and Graminaceæ have been coined, while the substitution of Pinaceæ for Coniferæ to include Taxus cannot be accepted; further, it would have been less perplexing to many botanists to find the nomenclature if not the sequence of the last edition of Babington's "Manual." Doubtless the last point has received the consideration of the reviser, who has rendered another service to botany by placing on record his conceptions based on many years' constant study of British plants.

Yorkshire Type Ammonites. Edited by Mr. S. S. Buckman. Part I. Pp. i–xii, *i–ii*, plates 12, and descriptions Nos. 1–8. (London: W. Wesley and Son, 1909.) Price 3*s*. 3*d*. net.

IT is intended that this work shall appear in about sixteen parts. The object of the publication is to give an adequate pictorial and critical revision of the type-specimens of Jurassic ammonites from Yorkshire which were unsatisfactorily described or figured by the early authorities Young and Bird, John Phillips and Martin Simpson. The treatment is similar to that in the well-known "Palæontologia Universalis," and the excellent illustrations in collotype process are from photographs of the actual specimens, mainly by Mr. J. W. Tutcher. In addition to a reprint of the original diagnoses, supplemented by useful critical remarks, the editor has supplied a clearly arranged and concise account of the comprehensive system of terminology which has been adopted by those who have made the most advanced studies of ammonite-development. He has also added some original and suggestive remarks on the cyclical development of the shell-form. In another section of the work there are useful notes on generic names. Twelve plates are issued in the present part, with text relating to eight species, and the introductory matter is uncompleted. This work will prove indispensable, not only to those who take a serious interest in Yorkshire geology, but to all students of Jurassic ammonites.

Klimatographie von Osterreich. Part IV. *Tirol und Vorarlberg.* By Dr. H. v. Ficker. Pp. vi+162. (Vienna: Gerold und Komp, 1909.)

THIS volume forms part iv. of the valuable handbook on the climatology of Austria which is being issued by the Zentralanstalt für Meteorologie und Geodynamik of Vienna. It deals with the Tyrol and Vorarlberg, and has been prepared by Dr. H. v. Ficker with the cooperation, in the botanical and zoological part, of Prof. von Dalla Torre. The region under discussion is one of special interest by reason of the great contrasts which it presents. The North Tyrol is formed by the valley of the Inn and its tributaries. Here we have a long valley running east and west, and protected both to north and to south by high mountains. Föhn winds are frequent, and have a decided effect in raising the mean temperature. As a result many flora and fauna which are characteristic of more southern latitudes manage to persist. In the South Tyrol the main valleys, Etsch and Eisach, run from north to south. To the north they are protected by the central Alpine range, but to the south they are freely open to the plain of the Po. The Pustertal, running west to east, forms a region by itself. It is freely exposed to winds from the east, which have a decided influence in lowering the winter temperature. Finally, in Vorarlberg we have again a different arrangement. The valleys slope down to the north-west towards Lake Constance. This fact has an important influence on the climate, as the prevailing wind over this part of Europe is from north-west. The climatological data are discussed on the lines suggested by Hann in his "Lehrbuch der Klimatologie," which have been followed also in the previous volumes of the series. The peculiarities of each region are clearly set out and contrasted with one another.

The Scholar's Book of Travel. Part i., The British Isles and Readings in Physical Geography. Pp. viii+197. Part ii., Europe. Pp. viii+198. Part iii., Other Lands. Pp. viii+200. Part iv., The British Empire. Pp. viii+200. (London: George Philip and Son, Ltd., n.d.) Price 1s. 3*d*. each.

Cambridge County Geographies. Cambridgeshire. By Prof. T. McKenny Hughes, F.R.S., and Mary C. Hughes. Pp. xiii+271. (Cambridge: The University Press, 1909.) Price 1s. 6*d*.

THE teaching of geography in this country is undergoing a complete change. Efforts are being made in every direction to create interest in the human aspects of geography and also to render the study of the subject a training in the methods of science. The pupil is no longer merely set to learn by heart lists of geographical data, but he is encouraged by the study of maps, by simple experiments, and by reference to original sources, to discover and to arrange facts for himself, and by his own efforts to arrive at simple, broad geographical principles.

"The Scholar's Book of Travel" is designed to provide the young pupil with literary extracts from books of travel, and to give him the opportunity of learning from first hand accounts about this and other countries. The four little volumes should serve a distinctly useful purpose, especially as they will probably send the learner to the excellent books from which the extracts are taken. The majority of the excerpts are from the older writers—Livingstone, Speke, Mungo Park, Defoe, Kingsley, Darwin, to name a few—but the beauty and interest of the passages will doubtless make the reader desire to read the works of modern travellers.

The volume dealing with Cambridgeshire follows the general lines of the series to which it belongs, and these have been described on previous occasions. The authors provide an excellent account of an interesting county, and readers will find that though called geography the book gives particulars of the geology, history, antiquities, architecture, and the roll of honour of the district.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Fertilising Influence of Sunlight.

THE past history of agricultural science furnishes several examples of belated explanations of the utility of practices the value of which has long become a tradition among practical men. The explanation of the value of leguminous crops in agriculture is a good example. While the recognition of the *rôle* of these crops in increasing the nitrogen supply in the soil has done much to improve agriculture in new countries, it has only served to provide a scientific approval of the cultural practices of ancient civilisations, such as that of India, where from time immemorial it has been the custom to grow leguminous crops in the rotation and also as one of the constituents of the mixed crops cultivated in many parts of the country.

Agricultural science has recently provided another explanation of an ancient Indian practice. In the *Journal of Agricultural Science* of October last, Drs. Russell and Hutchinson have found that partial sterilisation of the soil by heating or by poisons leads to an increase in the supply of nitrogenous compounds and to increased fertility. These investigators state that partial sterilisation of the soil kills off the phagocytes which live on bacteria, and also large organisms inimical in other ways to bacteria. At the same time the soil bacteria are killed off, but the spores remain which germinate and rapidly multiply when the soil is moistened. The new bacterial cultures increase at an enormous rate, and the resulting nitrogenous plant food becomes so great that plant growth is greatly stimulated. The authors then go on to state (p. 120):—"There is reason to suppose therefore that the large destructive and competing organisms will be found of common occurrence in ordinary soils, checking the beneficial bacteria and limiting fertility. An important practical problem arises: is it possible to suppress them in ordinary field soils by any economical and practical process?"

The practice among many of the best cultivators in the Indo-Gangetic plain furnishes a most emphatic affirmative to the above question. It has been the practice of the ryots for centuries past to expose the alluvial soils of the plains of India to the intense heat and light of the Indian hot weather in April and May. The beneficial result on the succeeding crop is extraordinary, and has all the effect of a nitrogenous manuring. It is much more than probable that the result of this weathering is a partial sterilisation of the soil, and that Russell and Hutchinson's explanation is the correct one. Except in market-garden crops near the cities and in crops like sugar-cane and tobacco, manures are but little used in India. The growth of leguminous crops and the weathering of the soil during the hot season appear to be sufficient to keep up the fertility. More nitrogenous manure would no doubt be an advantage, but a great deal could be done by the cultivators themselves in weathering the soil during the hot weather in a more efficient manner than at present.

The extended use of cheap light iron soil-inverting ploughs during the hot, dry weather after the *rabi* harvest would do much to bring about a better exposure of the soil to the sun, and a more complete sterilisation. The wooden ploughs now in use are not adapted to open up the heavier lands unless they are moistened by rain, and in consequence a large area of the arable land is not ploughed at all until the monsoon. We consider one of the greatest improvements possible in Indian agriculture would be to impress on the ryot the value of weathering all arable lands in April and May to a much greater extent than is done at present. When iron has taken the place of wood in the ploughs of the Indo-Gangetic plain, it will be possible for the cultivator to take the fullest advantage of, and greatly extend, their present most admirable practice. In collaboration with Mr. H. M. Leake, economic botanist to the Government of the United Provinces, we have in progress a series of experiments in which the practical effect of weathering during the hot months on both the yield and quality of wheat is being ascertained.

Pusa, November 18, 1909.

A Note on the Gilded Metal-work of Chiriqui, Central America.

Among the minor ethnological problems which America offers in such variety, not the least interesting is that of the origin, significance, and method of production of the specimens of gold-work found so abundantly in certain parts of Central America and in the north-western regions of the southern continent.

The earliest European voyagers who reached the shores of the New World directed attention in their narratives to the gold ornaments and little images of "frogs, birds and men" found in the hands of the natives, and, as Humboldt urged long ago, arguing erroneously from the accumulated riches of generations of savages, they attributed great mineral wealth to the newly discovered lands, giving them such sounding names as Costa Rica and Castillo del Oro.

Articles of gold alloy are widely distributed throughout South America, and vary as greatly in artistic and technical execution as in the purity or baseness of the metal from which they have been fashioned. This metal-work has long been known to students, as well as to treasure-hunters, and is of so extraordinary a character that it at once attracts attention. Running riot, heedless of the proprieties, its motives include every variety of zoomorphic design—human, bestial, bird, fish, or reptile; all types of life are represented, together with monstrosities and ambiguous shapes bordering frankly on the diabolical.

A certain amount of South American metal-work finds its way every year to England through dealers who purchase it from natives and speculators who make it their business to explore the ancient burial places. Practically the whole of this is melted down on account of its intrinsic value, but it is comparatively seldom that objects of artistic or archæological interest are lost to science in this manner, by far the greater portion of the work being of the crudest description.

The present letter deals more particularly with the gilded metal-work of Chiriqui, on the southern boundary of Costa Rica, which presents features of peculiar interest. It has been studied carefully by Holmes, whose work on the subject, embodying references to the earlier literature dealing with it, is to be found in the report of the Bureau of Ethnology for the years 1884–5.

The immediate interest of the subject turns upon the occurrence of objects fashioned from copper-gold alloys of very variable composition, the latter metal being present in some instances in a proportion insufficient sensibly to alter the colour of the copper, whilst, nevertheless, the surface of the objects presents a burnished coating of fine and splendent gold. In many examples the film of precious metal is so slight that it has all the appearance of electroplated work, and many conjectures have been hazarded to explain the method by means of which the native artist produced the effect.

Holmes, in the treatise already cited, quotes, on the authority of Bollaert, a reference to the works of Acosta to the effect that the Indians of New Grenada gilded copper by rubbing it with the juices of certain herbs and afterwards subjected it to the action of fire, when it took the gold colour, but states that he had not been able to find the passage in question. The present writer has also searched the pages of Acosta in vain, but it is probable that Bollaert quoted from memory the following passage in the "History of the Indies" of Gonzalo Fernandez de Oviedo (Edit. Amador de los Rios, vol. iv., p. 189), where that writer says, freely to translate the paragraph:—"I would wish to say how the Indians [of the Antilles, and especially those of Hayti] know well how to gild the little things they make of copper, very yellow like gold. They have in this such skill and excellency, and give such a deep lustre to that which they gild that it seems to be good gold of 23 carats or more by its colour when it leaves their hands. This they do with certain herbs, and is such a great secret that whoever of the goldsmiths of Europe or of any other part shall find it out, he will be a very rich man, and that in a very short time if he uses this manner of gilding." The old historian of the Indies made efforts to learn from the Indians this secret process, but they excused themselves on the plea that the herbs made use of were unknown to them, and that the small quantity they possessed of them came from very distant countries.

"It is not impossible," says Holmes, "that an acid may have been applied which tended to destroy the copper of the alloy, leaving a deposit of gold upon the surface, which could afterwards be burnished down. . . . It is possible that the film of gold may in some cases be the result of simple decay on the part of the copper in the alloy . . . but the surface in such a case would not be burnished, whereas the surfaces of the specimens are all neatly polished."

The operation above mentioned, whereby the apparent quality of articles of gold alloy is improved by the artificial enrichment of the superficial layer, is one frequently practised among goldsmiths, who term it "colouring." A hot process, involving the use of fused salts, is generally made use of (*vide* T. K. Rose, "Metallurgy of Gold," edit. 1906, p. 19; W. T. Brantt, "Metallic Alloys," London, 1896; and Gee, "Goldsmith's Handbook," 1881).

Considering it probable that a germ of truth lay in the information given by the Indians to Oviedo, the writer made several experiments of a simple character to endeavour to clear up this point. It was found that by acting upon a base alloy with dilute nitric acid, a black lustrous film of gold could be readily obtained by removing in solution a portion of the copper. By heating the object thus treated out of contact with air, the black film of gold is annealed, changing to the yellow modification, and is left in a condition to be readily burnished with any suitable implement, for example, a water-worn pebble of quartz.

The mineral acids being, presumably, unknown to the craftsmen of pre-Colombian America, advantage was taken of the solubility of copper in organic acids in the presence of air, and after a few successful preliminary experiments with the pure chemical products, various acid plant juices, the "herbs" of Oviedo's Indians, were tried, and fully answered expectation. There can be little doubt that the Indians had no need to ransack "distant countries" for the wherewithal to gild their ornaments; but every craft has its mysteries.

It was found that among the various organic substances tried in the course of the experiments few effected the required reaction so readily as urine, which, with free access of air, rapidly covers the surface of the alloy with a coating of hydrated copper salt readily soluble in acid plant juice. When performed with the aid of these natural reagents, the operation is a very tedious one, the gold film, in the case of base alloys, taking months to acquire sufficient substance to admit of being burnished; but time signifies little to the savage.

In conclusion, although not desirous of affirming that the procedure described was that invariably followed by the Indians in the production of gilded work, the writer is decidedly of the opinion that their operations broadly followed the lines indicated in the present letter.

Oswald H. Evans.

"Arauco," South Harrow, February 1.

Suggested Common Day of Meeting for London Societies.

Will you permit me to make a suggestion regarding the days of meeting of learned societies in London? At present these days seem to be selected in a very arbitrary manner, with the result that the provincial members of the societies are often called to London on several days during the same week. For instance, last autumn I ought to have attended no fewer than four such meetings during the same week, namely, on Monday, Tuesday, Thursday, and Friday. It is, of course, impossible for the majority of provincial members of London societies to give up so many days—we are generally compelled in such circumstances to abandon all the meetings. By some curious law of chance, moreover, it generally happens that two meetings occur with just an interval of one day between them, which makes it still more difficult to attend either.

Would it not be possible to fix one day, namely, Friday afternoon and evening, as a general day of meeting for the societies? This would, I feel sure, allow many provincial members to come down to London for the occasion, partly because they could merge the Friday with their "week-end," and partly because they might have the chance of attending several meetings the same afternoon and evening. I doubt whether such an arrangement would inconvenience many of the London members; but, even if it does, the London members might perhaps be willing to give way, because to them, in any case, attendance is much more easy than it is to men who live perhaps hundreds of miles away. I have discussed the matter with several friends in Liverpool, all of whom seem to be favourably impressed with the idea. RONALD ROSS.

Johnston Tropical Laboratory, University of Liverpool, February 5.

The Meaning of "Ionisation."

IN his interesting notice concerning the work of Arrhenius, published in NATURE of February 3, Prof. Walker, in a somewhat ambiguous manner, refers to "the notion and practical definition of degree of ionisation" as the great positive contribution of the distinguished physicist. "Whatever be our views of the origin and nature of ions, we must" . . . —he says—"have recourse to the notion of degree of ionisation." It is a little difficult to see how we are to have recourse to a notion if we are not clear what view that notion is based upon and includes. To appreciate Prof. Walker's position, it is essential that we should know precisely what meaning he attaches to the words I have quoted—what conception underlies them. I would beg Prof. Walker to tell us, in clear, unmistakable terms, what exactly he would have us understand by the word *ionisation*.

When the Royal Society has completed its Catalogue of Scientific Papers of the last century, it will doubtless be compelled to prepare a dictionary in explanation of the terminological inexactitudes to be found in its Proceedings and other journals; of these, *ionisation* will be one of the most difficult to interpret. Prof. Walker will render real service if he will tell us in what sense or senses he uses the word throughout his notice; does he or does he not use it as connoting explicitly the separation of a substance in solution into several portions, each capable of acting as a distinct kinetic unit? This, I believe, was the doctrine enunciated by Arrhenius in 1887, and which, if I mistake not, he still professes. Does Prof. Walker advocate such doctrine?

HENRY E. ARMSTRONG.

PROF. ARMSTRONG and I look at *ionisation* from different points of view. He is chiefly interested in an interpretation of the process and phenomena of ionisation in terms of the kinetic molecular theory. I am chiefly concerned to have a theory, whatever be its exact mechanical interpretation, which is capable of being mathematically formulated and of acting as a guide in quantitative investigation. My position, in short, is that of the astronomer who is content to have Newton's law for practical purposes, and only takes a speculative interest in theories of the nature of gravitation.

Possibly the best analogue in physics to Arrhenius's theory of electrolytic dissociation is van der Waals's theory of the continuity of the gaseous and liquid states. Van der Waals's theory can be put in the form of a comparatively simple equation which is very successful in representing the facts in broad general outline, though in many cases it proves to be imperfect in detail. Although the kinetic molecular assumptions on which van der Waals based his theory may be questioned, his equation will remain an important aid to investigation in its special domain until it is superseded by another of comparable simplicity and of greater comprehensiveness.

JAMES WALKER.

The Invention of the Slide Rule.

IN NATURE of January 13 (p. 307) Dr. Alexander Russell, in writing of the invention of the slide rule, says:—"Supporting the latter view is the fact that he (Oughtred) published (1633) his 'Mathematicall Recreations' under the pseudonym of Henry Van Etten." This evidently implies that Oughtred was the author of the said "Mathematicall Recreations," whereas the very title of the work shows that it was a translation, and not an original contribution. It reads:—"Mathematicall Recreations; or a collection of sundrie problemes and experiments in arithmeticke, cosmographie, astronomie, architecture, chimistrie, &c., extracted out of the ancient and moderne philosophers, *now delivered into English tongue* with the examinations, corrections and augmentations by W. Oughtred."

The italics are ours. The translation was made from the French of Henry Van Etten's "Recreation Mathematique, composee de plusieurs problemes, plaisants et facetieux, en fait d'Arithmétique, Geometrie, Mecanique, Optiq.; et autres parties de ces belles Sciences." The accents are missing in the title-page. The work was published in Paris in 1624. The name of Henry Van Etten is indeed a "pseudonym," but it is that of Jean Leurechon (1591–1690), a French Jesuit of uncommon mathematical versatility, and not that of William Oughtred (1574–1660), an English divine of no less uncommon mathematical ability.

Transit of Halley's Comet.

MAY I point out that at the time of the transit of Halley's comet the sun will be above the horizon at the North Cape? The Cape is distant 18° 49′ 20″ from the pole, and the declination of the sun at midnight of May 18 will be 19° 31′ 42″; adding 27′ 22″ for refraction, the sun's altitude at midnight would be 1° 9′ 44″, and the altitude would increase before the first contact, which will take place at 16h. 6m. local time. The Cape rises to a height of 968 feet, and there should be a very fair sporting chance of seeing something of whatever there may be to see during the sixty minutes' duration of the transit.

C. S. TAYLOR.

Banwell Vicarage, Somerset, February 11.

Dangerous Lecture Experiments.

ALTHOUGH it is no part of my duty to teach chemistry, I have on several occasions had to perform an experiment which Mr. Marle quotes (p. 428) as being dangerous, viz. the collection of hydrogen from the action of sodium on water. I can fully endorse his warning. Twice a violent explosion took place; but I found that if the piece of sodium is carefully cleaned so that all its surfaces are bright, and cold water used, the experiment can be carried out in safety. I do not know if these important details have found their way into the practical manuals in use in chemical laboratories. If not, I trust that this experiment is not one that beginners are directed to make.

M. D. HILL.

Eton College, Windsor, February 11.

Aged Tadpoles.

LAST year I reared about five thousand tadpoles, and, dividing them into twenty portions, brought most of them to the frog stage. As they matured, and the numbers became smaller, the survivors were gradually brought together again into a few vessels, finally into one. Of those which were in the tadpole stage in November, none changed to frogs. They died one by one until only two are left. These are quite healthy—active feeders with long tails and hind legs, but no appearance of fore legs. Perhaps some of your readers will be able to say whether it is usual to have tadpoles a year old, and whether one may expect any change to take place now—whether, perhaps, like Axolotl, they may not exhibit the power of reproducing their own kind if they remain alive.

Carrick Academy, Maybole, N.B.

SOUTH SEA SAVAGES.[1]

MR. H. W. WALKER, in an account of his wanderings among the savages of Fiji, the Philippines, Papua, and Borneo, has not set himself the task of dealing scientifically with ethnographical details. He has aimed rather at giving a general impression of native life and environment in some of the more out-of-the-way corners of the island world. In this aim he has admirably succeeded, and his book affords a vivid picture of the people and regions which he has endeavoured to describe.

The first chapters recount a visit to Ratu Lala, chief of the Fijian island of Taviuni. Here, under the thin veneer of civilisation produced by two years' schooling at Sydney, was found a man at heart a savage, who could boast of how he treated his jester as a fish and played him with hook and line, or pegged a woman on an ant-hill, smearing her with honey to make the ants bite.

In this and the following chapter on the ex-cannibals of Na Viti Levu, "who would still like to eat man if they got the chance," Mr. Walker describes Fijian dwellings, customs, and war ceremonies.

In the Philippines the author visited Pampanga, in North Luzon. In the mountains near Florida Blanca he stayed with some friendly Negritos, of whose appearance, dress, ornaments, and weapons he gives an interesting account. While staying here Mr. Walker heard of a strange people called Buquils, who lived further in the mountains, and were reported to be Negritos with long smooth hair. The women were said to have beards. Mr. Walker made a difficult mountain journey with his Negrito friends to try to find these people. When almost in touch with the Buquils, however, the Negritos refused to proceed further until they had sufficient fighters to avenge the killing of their fellow-tribesmen who had ventured into the Buquil country. Mr. Walker had to catch his steamer, and could not wait for them.

Mr. Walker next describes his adventures during a Government punitive expedition against the Dobodura tribe in North-east British Papua. Although on the warpath, the author was not unmindful of natural scenes, and gives some interesting notes on plants, birds, and forest scenery. Mankind was less pleasant, and as the party passed along they saw "in each village plenty of human skulls and long sticks with human jawbones hanging upon them." A brisk description is given of the skirmishes and night attack. Once the author was separated from his party, and had some lively anticipations of taking a too prominent part in a cannibal feast. For the Dobodura were cannibals of a very pronounced type, and the author's headings and items in these chapters are suggestive of a ghastly nightmare. "Pigs shot to prevent them from being cooked alive.—Revolting relics of cannibal feast.—Doboduras eat their enemies alive.—Method of extracting the brains.—Man better than pig.—Carriers ask leave to eat one of the slain.—Horrible barbarities of the Doboduras.—Unpleasant anticipations.—Two miners roasted alive." Incidentally, in these chapters Mr. Walker bears witness to the smartness, pluck, and good humour of the native Papuan police. In the same region of Papua, the author, with Messrs. Monckton and Acland, discovered a peculiar tribe of flat-footed lake-dwellers, whom report had credited with webbed feet like a duck. There was some truth in the report, and Mr. Walker gives a description of the people and an account of their customs quoted from Sir F. Winter.

A Negrito Family. From "Wanderings among South Sea Savages," by H. Wilfrid Walker.

The next chapters relate to the head-hunting Sea

---

[1] "Wanderings among South Sea Savages and in Borneo and the Philippines." By H. Wilfrid Walker. Pp. xvi + 254. (London: Witherby and Co., 1909.) Price 7s. 6d. net.

Dayaks in Sarawak. The author gives interesting notes on Dayaks and heads, and a gruesome story of a head-hunting exploit. Later he lived with Dayaks on the Sarekei River. The chapter in which he describes his life among them is one of the best in his book.

The final chapter is an account of a visit to the famous birds'-nest caves of Gomanton, in British North Borneo. Of these caves and their inhabitants —birds and bats—an interesting account is given. Incidentally also a good word-picture is given of Borneo river and jungle life.

Mr. Walker has told his story in a very natural and entertaining way. There are no dull pages. Some of his cannibal and head-hunting tales may be *horrendum dictu*, but even these are to be matched by facts culled from many an official report on these wild people of the South Seas.

The book is well illustrated by forty-eight illustrations from photographs, and has a useful index.

S. H. R.

THE FRENCH ANTARCTIC EXPEDITION.

THE French expedition under Dr. Jean Charcot, on board the *Pourquoi Pas?* returned to Punta Arenas at the end of last week. The early return of the expedition, some weeks before it was expected, is due to a series of misfortunes which limited the range of the expedition's operations.

It will be remembered that this is the second of Dr. Charcot's Antarctic voyages. In 1903–5, on board the *Français,* he carried out an expedition along the west coast of Graham Land, south of Cape Horn, wintering on Wandel Island, in about 65° S. lat., and continuing the voyage to a point off Alexander I. Land in about 68° S. lat. Apart from the additions made to cartographical knowledge of some of the islands off Graham Land, the expedition was notable for the scientific observations and collections secured in the departments of hydrography, terrestrial magnetism, biology, botany, and geology.

Dr. Charcot's latest expedition was designed to extend the work done in 1903–5. The programme contemplated another cruise among the islands off the west coast of Graham Land, whence it was hoped to continue the voyage westwards in the direction of King Edward VII. Land; it was also proposed to make excursions southwards to investigate the character of the supposed Antarctic continent, and for this purpose the *Pourquoi Pas?* carried a number of specially designed motor sledges. The expedition was liberally subsidised (24,000*l.*) by the French Government, and the ship, a barquentine with an auxiliary engine of 550 h.p., was specially built for the voyage. The French Naval Department, the Paris Museum, and the Prince of Monaco contributed to the scientific equipment, and the scientific staff included, besides Dr. Charcot, who belongs to the medical profession and is an experienced bacteriologist, specialists in hydrography, oceanography and meteorology, tidal and chemical observations, geology and glaciology, natural history, and terrestrial magnetism.

The expedition sailed from Havre in August, 1908, and from Punta Arenas in the following December. Supplies of coal were taken on board at Deception Island (lat. 63° S.), in the South Shetlands, which has become an important rendezvous for whalers. On resuming the voyage the *Pourquoi Pas?* ran aground, and after being re-floated lost her rudder in collision with icebergs. The voyage, however, was continued to Adelaide Island, south of the 67th parallel, and the adjacent coasts were explored for a distance of 120 miles to Alexander I. Land. Being unable to find a safe anchorage, the expedition then returned north and spent the Antarctic winter of last year off Petermann Island, south of the 65th parallel. Though attacked by scurvy and other diseases, the explorers carried out several excursions, and made a careful study of the glaciology of the region. On the return of summer they continued their explorations among the South Shetlands, again visiting Deception Island, and also Bridgman Island (62° S.). The course of the *Pourquoi Pas?* was then directed south and west, and the expedition succeeded in reaching Peter I. Island (lat. 69° S., long. 90° W.). Ultimately the voyage was extended, between the 69th and 71st parallels, to long. 126° W. King Edward VII. Land extends between the 150th and 160th meridians of west longitude.

Graham Land projects northwards from the Antarctic Circle towards Cape Horn as a great tongue of land with numerous adjacent islands. It has been visited by several expeditions, but its connection with the Antarctic continent is still a matter of speculation. Westwards, in the region south of the Pacific Ocean, Cook and Bellingshausen sighted stray patches of land or appearances of land, presumably part of the Antarctic continent, but the continuous coast has never been definitely traced. Geographically, the value of Dr. Charcot's expedition consists in the work he has been able to accomplish in linking up and defining more clearly the character of these stray patches of coast. Exactly what have been the results of the expedition in this connection can only be determined when his charts become available. As on the occasion of his former expedition, the most valuable feature of the results will probably be the scientific data collected respecting the magnetic, meteorological, hydrographical, and geological conditions in the regions south of Cape Horn. Dr Charcot was unable to make use of his motor sledges for penetrating the Antarctic continent.

RADIUM IN DISEASE.

ATTENTION has again been directed to the possibilities of radium as a curative agent by Sir William Ramsay (at the Authors' Club on Monday), and by Sir Lauder Brunton (in the *Lancet*).

The supply of radium available for the treatment of disease is still so limited that the therapeutic usefulness of this agent has not yet been fully determined. No sooner were indications noted of a prospect of relieving cancer by the use of radium than all the radium obtainable was devoted to this purpose; consequently, its action in less serious ailments is still almost unknown.

In the treatment of cancer, radium has usually been employed in the form of crystals of the bromide. These crystals are contained either in a sealed glass tube or in a button with a covering of thin glass, aluminium or mica. Recently the crystals have been spread in a thin layer upon a flat surface and covered with a layer of varnish. Such buttons and spread preparations are suitable for application to the surface of the body. The glass tubes may be inserted into the interior of tumours, or into orifices of the body; thus, they may be placed in the mouth or nose, in the œsophagus (within a rubber tube), in the rectum, or in the cervix uteri.

Of the three types of radiation given off by radium (the alpha, beta, and gamma radiations), the view commonly accepted is that the gamma rays have a selective action, destroying cancer cells while leaving the normal cells of the part intact, while the alpha and soft beta rays destroy all cells indiscriminately. Means must accordingly be used to prevent the alpha and soft beta rays from reaching the body. A filter consisting of one millimetre thickness of lead is suitable.

As it is risky to send a patient away with a valuable tube of radium crystals within his body, sealed glass tubes of radium emanation have recently been used (*Lancet*, December 11, 1909). They are enclosed in lead tubing one millimetre in thickness. These tubes of emanation do not differ from the crystals in the rays they emit or in their action; there is, however, one important difference; the radio-active strength of the emanation tube decays according to an exponential law in such a way that the strength is reduced to one-half at the end of about four days. Such tubes, of about 10 milligramme strength, may be placed in contact with a cancerous growth (say in the rectum) and allowed to decay *in situ*. At the end of a fortnight they may be removed, as being then too weak to be of further use.

Other methods have been tried in a few cases; thus, dilute solutions of radium bromide have been given by mouth, and water in which radium emanation has been dissolved has been injected subcutaneously.

Coming now to the results obtained, the accounts are very conflicting. Undoubted relief has been obtained in a considerable proportion of the cases; cancerous tumours have diminished in size, and have disappeared altogether in some cases. But some of the earlier cases reported as cured have since been found to relapse; in some cases the growth has recurred in the original situation, while in others cancerous deposits have formed in internal organs. It seems fairly certain that in some cases cancerous growths may be cured in their early stage by radium, but it is not yet justifiable to attempt this unless the patient is so feeble (through heart disease or Bright's disease, for instance) that the removal of the growth by operation could not be undertaken.

When the surgeon has declared a case inoperable, radium (or Röntgen ray) treatment is used as a last resource, and the attempt is usually a desperate one. It is something, then, to be able to report the complete disappearance of malignant growths in some of these cases, even though the final result is not a cure. The local treatment of cancerous growths does nothing to prevent dissemination of the disease in the internal organs, and it is with the idea of achieving this result that attempts have been made to cause radium or its emanation to circulate through the body. In doing so it must be remembered that the alpha radiation is giving out its full energy in the body; and since this radiation possesses about a hundred times as much energy as the beta and gamma radiation together, it is clear that for practical purposes we may disregard the effect of the gamma radiation in this connection. Now, we started with the postulate that the alpha rays are indiscriminately destructive, so that if enough is allowed to circulate in the body to destroy cancer cells, the normal cells of the body will also be destroyed. It must be allowed, however, that the observations upon which this postulate are founded are by no means conclusive, and though there is no doubt that the alpha and soft beta rays destroy normal cells far more readily than is the case with the gamma rays, it may still be true that they too possess some degree of selective action, if the dosage be regulated with sufficient accuracy.

This branch of therapeutics is still in its infancy, and it would be a mistake either to raise delusive hopes because some cancerous growths have been made to disappear under its use or to declare it useless because disappointments are common. One disease, rodent ulcer, is cured by the use of radium in the great majority of cases, only a few rodent ulcers proving refractory to its use. There are, however, other methods of curing rodent ulcer. The further development of this branch of medical science will be watched with great interest.

A SIMPLE METHOD OF ELECTROPLATING.

At a meeting of the Royal Society of Arts on February 2, a paper by Mr. A. Rosenberg was read upon an improved method of electroplating. Mr. Rosenberg dispenses altogether with the plating bath and all external sources of electricity. The plating is carried out simply by rubbing on a powder moistened with water. The process is really a refinement of the old contact method. It will be remembered that in this process a piece of metal which it is desired to plate upon is immersed in an electrolyte, for example, one containing a silver solution. In contact with this metal a more electropositive one is placed, also dipping into the electrolyte. This metal, usually zinc, passes into solution, and an electric current thereby is generated. The silver is then plated-out upon the less electro-positive metal.

Mr. Rosenberg employs his electro-positive metal in the form of a fine powder, and generally uses magnesium. This is mixed with a metallic salt or with the powdered metal it is desired to plate-out, and ammonium sulphate or other ammonium salt. In order to plate a piece of metal the powder is moistened with water and rubbed over its surface by means of a piece of rag or a brush. By this means adherent and bright deposits are obtained in about one minute, the thickness of the deposit depending upon the time employed and the quantity of powder used.

The magnesium, being strongly electro-positive, reacts with the moist electrolyte, and goes into solution, causing the metal to be plated-out upon the metallic surface which is being rubbed. In other words, each particle of the powdered magnesium may be said to function as a minute anode. One of the difficulties in electroplating is to plate a substance upon itself. It is easy enough when plating has once commenced, say on a spoon, to give it almost any thickness of deposit; but if the spoon is once withdrawn from the bath and used, it cannot be plated further without first stripping off the old deposit. Mr. Rosenberg claims that with his process this difficulty does not occur.

Another great difficulty in electroplating is the cleansing of the article to be plated; the least trace of grease, even that produced by handling, for example, will prevent an even and adherent deposit. Consequently, articles have, as a rule, to be chemically and mechanically cleaned before being put into the plating bath. With the powder, "Galvanit," of Mr. Rosenberg this is not necessary, because the act of rubbing the powder carries out its own cleansing.

The author's object has been to produce a household method of plating. Thus, when the tinning of saucepans is worn out, the householder has only to polish the inside with the moist "tin Galvanit" to re-tin the saucepan. Spoons from which the silver-plating is partly worn can be re-plated. The "nickel Galvanit" can be used for bicycles and so on. Mr. Rosenberg demonstrated the process before the meeting by plating an iron tube with cadmium, a copper tube with nickel, a penny with silver, and a brass tube with tin.

"Galvanit" can also be used for nickel-facing electrotypes. The process is certainly ingenious, and will no doubt be found useful for small work, but it is hardly likely to enter into competition with ordinary electroplating for large work or for irregular articles. Nor is it likely to be employed in cases where heavy coatings of metal are required, because it would not be an easy matter to rub on sufficiently evenly to obtain uniform and thick deposits. F. M. P.

UNIVERSITY COLLEGE, LONDON.

APPEAL FOR NEW CHEMICAL LABORATORIES.

MANY old students of University College, London, and others familiar with the work done in the chemical department of the college, will be interested in the appeal which has just been made for funds for new chemical laboratories.

The letter which Lord Rosebery has written as Chancellor of the University, and the statement circulated by Sir Henry Roscoe, as chairman of the Equipment and Endowment Fund Chemistry Appeal Committee, serve to bring into high relief the urgent need at University College for improved and more extensive accommodation in its chemical department, both for teaching and research purposes.

While, thanks largely to the generosity of Mr. Carnegie, the University of Manchester has recently become possessed of adequate and modern laboratories, and fine buildings possessing admirable accommodation for chemical science have been erected at South Kensington—to give two examples only—the University College laboratories date from 1871. Yet, despite material disadvantages, splendid work for chemistry has been accomplished in Gower Street under Graham, Williamson, Sir William Ramsay, and others.

In America to mention the need and to state the sum required would ensure its being immediately forthcoming, especially when it can in a sense be regarded as a means of celebrating the completion by Sir William Ramsay of twenty-one years of work at University College. In Germany, again, the State would see to it that so distinguished a chemist was not hampered by want of material or accommodation.

We are hopeful that a ready response to the appeal will be promptly forthcoming, and that very soon the necessary buildings will be in course of erection. The appeal, and Lord Rosebery's letter referring to it, are subjoined.

An Appeal for 70,000l. for the purchase of a Site and the erection of new Chemical Laboratories thereon at University of London, University College.

The chemical laboratories at University College, London, were for the most part built under the direction of the late Prof. Alexander Williamson in the year 1871. From time to time they have been re-fitted and supplemented to meet the demands of the subject and the increasing number of students in the department. It has been impossible in the present buildings of the college to provide the requisite additional accommodation in rooms immediately adjoining the main laboratories. Consequently, at the present time the department is scattered and inconvenient, and neither in planning nor equipment is it adequate for modern chemistry work. The average number of students in the chemical department for the last four sessions has been 261, of whom, on the average, 160 have been students in the junior classes, 68 students in the advanced laboratories, and 33 research students.

During the last four sessions, the college has been compelled to refuse students for want of room, even after making such arrangements as have been possible for the laboratory work of some students elsewhere. The number of those who desire to do research work under Sir William Ramsay and Prof. Collie has also increased to such an extent that additional accommodation is now a matter of urgent necessity.

The lack of adequate accommodation for the department of chemistry at the college has been carefully considered by the University and college authorities, and the conclusion has been arrived at that nothing short of entirely new buildings can meet the necessities of the case, a conclusion confirmed by the Treasury Commissioners at their last inspection of the college, and also by the University inspectors.

The provision of new buildings for the department of chemistry will greatly benefit other branches of university study now hampered for want of room. The space in the present buildings vacated by the department of chemistry will go some way towards supplying the deficiency of space for other subjects.

It was originally proposed to provide the requisite accommodation for chemistry by erecting the north-west wing of the college on the Gower Street frontage, but a more convenient site has been found fronting Gower Place on the north side of the present buildings of the college. This site has a frontage of about 316 feet and an average depth of 66 feet, with a superficial area of about 20,800 feet, and is suitable in every way for the erection of chemical laboratories. The Senate has acquired an option lasting for a short period to buy this site at an agreed price.

The erection of the north-west wing of the college would necessarily be expensive, because it must be built in Portland stone and correspond in elevation with the remainder of the quadrangle of which it would form part, and for these reasons it would not be suitable for chemical laboratories. It is estimated that the cost could not be less than 70,000l.

For this sum (70,000l.) not only could the freehold of the proposed new site be acquired, but a suitable building for the department of chemistry could also, it is estimated, be erected upon it.

If sufficient money is not immediately forthcoming to complete the whole scheme, the earlier subscriptions will be applied in purchasing the site.

The services to chemical science which have been rendered by Sir William Ramsay, the university professor of general and inorganic chemistry, who has recently completed twenty-one years' work at the college, and the important discoveries that he has made, are generally well known. In addition to these, the number of researches published during the past twenty-two years by members of the staff and students of the chemical department amounts to 331; of these, 72 have been carried out by Sir William Ramsay and collaborators. It is interesting to observe that while the total number of researches published from the department from 1887–1902 was 115, the number issued since 1902, when the laboratories were enlarged, to the present year is already 216.

It is the wish of Sir William Ramsay's friends and of his old students to see his desire for adequate and well-equipped chemical laboratories realised as speedily as possible.

This appeal for 70,000l. for new chemical laboratories is therefore made to all who are interested in the advance of chemical science, and also to all who desire to see university teaching in London developed in accordance with its needs.

Donations or subscriptions, which may be paid in instalments, should be sent to the chairman or the treasurer of the new chemical laboratories fund, and addressed to University College, London.

HENRY E. ROSCOE (*Chairman*).

Letter from the Chancellor of the University.

Dalmeny House,
Edinburgh.
January 23, 1910.

I earnestly hope that the friends of the University of London and the admirers of Sir William Ramsay will cooperate to ensure the success of this appeal for 70,000l. for an academical necessity.

Should the admirers of Sir William Ramsay alone take the matter up in proportion to their zeal and his merits, there can be no doubt of the necessary fund being raised.

But indeed those who are interested in the well-being of our university, either from their association with it or on high public grounds, will, I am sure, spare no effort to ensure the prompt erection of the chemical laboratories so urgently needed for its work.

ROSEBERY (*Chancellor*).

ASPECTS OF ASTRONOMY.

AT the anniversary meeting of the Royal Astronomical Society on February 11, the gold medal of the society was presented to Prof. Friedrich Küstner, director of the Royal Observatory, Bonn, for his catalogue of stars, his pioneer determination of the aberration constant from motions in the line of sight, and his detection of the variation of latitude. In his address as president of the society, Sir David Gill described the valuable work done by Prof. Küstner in each of these directions. He prefaced his remarks by saying:—

> Astronomy in one sense or another appeals to minds of widely different orders. To the mathematician it offers problems of infinite interest; but, as we all know, there have been most distinguished workers in the field of astrodynamics to whom the spectacular glories of the heavens do not appeal—to whom the first sight of an object like Saturn or a great star cluster as viewed through a good telescope brings no thrill, no insatiable desire to see more or to acquire or devise means for so doing. Such men are too apt to regard the art of observing as a mere mechanical operation that is unworthy of their practical study; but they are thus frequently placed in the position of having to employ observations about which they have not the capacity to distinguish between the good and the bad.
>
> There is a larger number of persons who are not wanting in the emotional response to their first telescopic sight of celestial objects; some of these acquire, or are driven to construct, instruments to indulge their awakened curiosity, and not a few of them afterwards do useful work as astronomical observers.
>
> The attributes of the great majority of astronomers lie between these two extremes; but the number of men who possess the true fire and natural capacity for the most refined original research in the field of astrometry is limited. Such men must have an inborn natural mathematical, mechanical, and manipulative aptitude; the critical faculty to discern the possible sources of error to which any class of observations may be liable, with the inventive capacity to devise means for their elimination; and that persistent patience and divine discontent with their own best efforts which alone can lead to the highest and most refined class of work.

NOTES.

THE following telegram from the Paris correspondent of the *Times* appeared in the issue of that journal for February 16:—"Paris, February 15.—According to a communication made yesterday to the Academy of Sciences by M. Lippmann, Mme. Pierre Curie, the widow of M. Pierre Curie, the discoverer of polonium and radium, has at last succeeded in isolating one-tenth of a milligram of polonium. In order to obtain this result, Mme. Curie, working in cooperation with M. Debierne, has had to treat several tons of pitchblende with hot hydrochloric acid. The radio-active properties of polonium turn out to be far greater than those of radium. It decomposes chemically organic bodies with extraordinary rapidity. When it is placed in a vase made of quartz, which is one of the most refractory of substances, it cracks the vessel in a very short time. But a no less distinctive quality of polonium is the comparatively rapid rate at which it disappears. Whereas it takes one thousand years for radium to disappear completely, a particle of polonium loses 50 per cent. of its weight in 140 days. The products of its disintegration are helium and another body, the nature of which has not yet been ascertained, but Mme. Curie and M. Debierne are inclined to believe it to be lead. Its identity, however, will shortly be established, and at the same time science will have had the experimental proof of the transformation of a body which had been believed to be elementary."

WE learn from the Paris correspondent of the *Chemist and Druggist* that the administrative council of the Pasteur Institute has decided to establish a laboratory for the study of radio-activity and its therapeutic applications. This laboratory will adjoin the Oceanographic Institute there. The Pasteur Institute will devote to this object 400,000 francs of the Osiris Legacy. The University of Paris will give the land and find the rest of the money. Mme. Curie will be directress of the physical side of the laboratory, and the other section (researches as to practical applications of radio-therapy) will be under the direction of the Pasteur Institute. On a neighbouring site an extensive institute of chemistry is to be erected at the joint cost of the State, the city of Paris, and the Paris University.

A COMMITTEE has been formed with the view of promoting investigations into the nature and etiology of pellagra, a lethal disease which has become a terrible scourge in some countries of southern Europe and in many tropical or subtropical regions in other parts of the globe. The generally accepted notion is that the disease is caused by damaged maize; Dr. Sambon has, however, brought forward cogent reasons for regarding this theory as inadequate, and has pointed out that the seasonal prevalence and distribution of pellagra are compatible with its being a protozoal disease, which is spread by the agency of blood-sucking insects, probably sand-flies. It is intended to send Dr. Sambon, accompanied by properly qualified assistants, to a pellagrous region to carry on investigations on the etiology of the disease, and for this purpose it is hoped to raise a fund of 1000*l.*, towards which several subscriptions have been received, including a sum of 150*l.* from the Colonial Office.

ALL English chemists will join with their German colleagues in offering their congratulations to Prof. Julius Wilhelm Brühl on his sixtieth birthday, which he celebrated on Sunday last. Prof. Brühl's contributions to chemical science range over the whole of the subject. His first paper, on the substitution amido- and phosphido-acids, was published in 1875, and from that year, almost up to the present, his work exhibits an almost unequalled activity. During the last thirty-five years no fewer than ninety papers have been published by this extremely energetic chemist, and it is worthy of note that, with few exceptions, they are a record of his own personal work. A paper published in 1881, on the relations of the physical properties of bodies and their chemical constitution, was the first of a long series of contributions on a part of chemistry in which Brühl stands pre-eminent. Those who were privileged to be present at the lecture he delivered in London in 1905 will remember the excellent summary he gave, in faultless English, of his work on molecular refractivity. One paper, in the domain of pure inorganic chemistry, deserves special mention as illustrating the all-round character of his work. In this research, published in 1895, hydrogen dioxide was first prepared in a pure condition, its formula was for the first time established, and its physical properties determined. Prof. Brühl has very many friends in this country; indeed, it is scarcely too much to say that all who have met him, at the British Association and elsewhere, are his friends. He has a great love for this country, and an unprejudiced respect for the achievements of her men of science. All will be glad to know that he is recovering from the severe illness which has crippled his activity for the last two years, and hope that his renewed health will enable him to add still more to our knowledge of the most difficult and perhaps the most interesting problems in chemical science.

The first fertilised eggs of the plaice for the hatching season of 1910 were skimmed from the spawning pond of the Port Erin Hatchery on February 14.

The Dutch Government is reported to have voted the sum of half a million francs for the erection of a new institute of physical and mineral chemistry, to be under the direction of Prof. F. M. Jaeger, of the University of Groningen.

Prof. J. D. Van der Waals, of the University of Amsterdam, has been elected a foreign associate member of the Paris Academy of Sciences. Prof. Van der Waals has been a correspondant of the academy since 1900.

The French Physical Chemistry Society has elected the following officers for the present year:—President, Prof. G. Urbain, of the University of Paris; vice-president, M. L. Lapicque, of the same university; treasurer, M. A. Brochet; secretary, M. Ch. Marie.

We note with regret that the *Revue scientifique* announces the deaths of Prof. H. Dufour, professor of experimental physics and meteorology in the University of Lausanne, and of Prof. Karl Gottsche, director of the Hamburg Institute of Mineralogy and Geology.

It is announced in *Science* that funds have been raised by public subscription for the establishment of an astronomical observatory at Kamuki, Honolulu, to be used in the first instance for observations of Halley's comet. The observatory, however, will be permanent, and under control of the College of Hawaii.

Prof. G. H. F. Nuttall, F.R.S., Quick professor of biology in the University of Cambridge, has been awarded the Mary Kingsley Medal by the Liverpool School of Tropical Medicine. The medal is awarded "from time to time to those who have distinguished themselves in research in tropical medicine and allied subjects."

An International Congress on the Administrative Sciences will be held at Brussels on July 27–31, in the grounds of the International Exhibition. The Secretary to the British committee is Mr. G. Montagu Harris, Caxton House, Westminster, from whom further particulars may be obtained.

The annual meeting of the British Science Guild will be held at the Mansion House on Friday, March 18, at 4 p.m. Arrangements have been made for the fellows and members of the Guild to dine together at Prince's Hall, Piccadilly, on Friday, May 6. Mr. Haldane, the president of the Guild, will occupy the chair.

A telegram was received at Utrecht on February 14 from Mr. H. A. Lorentz, stating that his expedition having the object of penetrating into Central New Guinea from the south coast has been entirely successful. Mr. Lorentz reached the snow-capped range which had previously only been perceived dimly from the distance; he has climbed in these Alpine regions, and has discovered glaciers at an altitude of 15,000 feet. One of the last geographical secrets of the tropical regions has thus been opened, and exploration in detail will no doubt follow.

Speaking at the dinner of the Physical Society on February 8, Dr. Chree, president of the society, referred to the work of the society and to its increasing activity. The number of papers read before the society has become much larger of recent years, but he thinks there may be some improvement in the presentation of such papers. Generally speaking, there are three ways in which an author may be congratulated:—first, on producing valuable results; secondly, on the form in which they are put; and, thirdly, both author and audience may be congratulated when the reading has been accomplished. Of these three, the second is the most rare. Papers usually consist of 25 per cent. due to the author and 75 per cent. of material that preceded the paper. Authors are apt to neglect the 75 per cent., and to assume that the audience know all about it; also, when any mathematics appears in a paper, the author generally proceeds to put it upon the blackboard. This is not desirable, because a physicist's knowledge of mathematics is usually not good, and mathematical results are frequently not of great value. In some ways it would be better for authors to read each other's papers instead of their own. Dr. Chree also thought it would be of great advantage occasionally if the society could have a general discussion of a subject by a physicist well acquainted with that special branch of knowledge.

In the January number of *Man* Mr. T. A. Joyce describes a remarkable wooden statue brought by Mr. E. Torday from the Kasai district in West Africa. Up to the present the art of portraiture in the round, so far as Africa is concerned, has been supposed to be confined to ancient Egypt. This specimen, however, shows that the art extended to the Bu-Shongo nation. The present statue, which is evidently a portrait, represents the national hero, Shamba Bolongonga, who is said to have been 93rd in the dynasty of rulers, the ruling king at the present day being 121st. The work is in many ways remarkable, the treatment of the collar bones and the swelling curves of the trunk displaying an attempt at realism which hitherto was supposed to be entirely foreign to the African artist. Mr. Torday, who must have displayed considerable tact and enterprise in acquiring a historical relic of this kind, is to be congratulated on his success and on his liberality in presenting such a valuable specimen to the British Museum.

Dr. C. Hose, in *Travel and Exploration* for February, gives an account of his visit to the warlike Madang tribe, occupying a region in Borneo which has up to the present remained unexplored. These people, on account of their raiding propensities, have been a terror to their neighbours; but the visit of Dr. Hose has resulted in an arrangement which will, it is hoped, put a stop to this constant intertribal warfare. It is remarkable that this race judge the fitting season for planting their rice by the sun, and they have invented a curious mode of measuring time. This is a sort of gnomon, consisting of a post about a fathom high, a piece of string weighted at each end and thrown over the top showing when the post is perfectly straight. The length of the shadow is measured by a stick marked with notches gradually approaching one another as they recede from the pole. Having got so far, it may be asked why they have never invented the sun-dial. Dr. Hose explains this by the fact that the present instrument is more efficient, as in these latitudes there are many days near each equinox when a sun-dial would be useless.

Among the contents of No. 1 of the *Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg* for 1910 is an illustrated paper, by Mr. E. Nasonow, on the life-history and transformations of *Kermes quercus*.

The sea-bass (Serranidæ) of Japan form the subject of an article, by Messrs. D. S. Jordan and R. E. Richardson, published as No. 1714 of the Proceedings of the U.S. National Museum. A new species of the large genus Epinephelus is described.

WE are indebted to the authors, the Rev. C. E. Y. Kendall and Messrs. J. D. Dean and W. M. Rankin, for a copy of a paper on the geographical distribution of molluscs in South Lonsdale, reprinted from the *Yorkshire Naturalist* for last year. The dependence of the distribution of the various species on station, geological formation, &c., is fully indicated.

IN the Proceedings of the Academy of Natural Sciences of Philadelphia for November, 1909, Messrs. H. A. Pilsbry and J. H. Ferriss continue their account of the land and fresh-water molluscs of the south-western States, dealing in this instance with the fauna of the Huachuca Mountains of Arizona. In the same issue Dr. Pilsbry, this time in association with Mr. A. A. Hinkley, discusses the Melaniidæ of the Panuco River system of Mexico.

THREE Continental insects are added to the British fauna in the *Entomologist's Monthly Magazine* for February, Dr. D. Sharp recording the Mediterranean beetle *Crepidodera impressa* from Hayling Island and *Galerucella pusilla* from the New Forest and elsewhere, while Mr. E. A. Butler chronicles the occurrence of an example of *Cyrtorhinus geminus*, a Scandinavian and Livonian hemipterid, at Broxbourne, and also mentions a second British specimen of the same species preserved in his own collection.

THE January number of the *Museums Journal* contains a summary of the correspondence which has recently appeared in the *Times* with regard to the administration of the natural-history branch of the British Museum. At the conclusion of the summary the opinion is editorially expressed that the director of the natural-history departments should be independent of the director and principal librarian at Bloomsbury. If the separation of the two establishments were carried out, no one, so far as we are aware, has suggested a suitable and adequate title for the one at South Kensington. "Natural History Museum" is obviously insufficient, except when used in connection with this country alone.

AT the commencement of a monographic revision of the Strepsiptera, published as Bulletin No. 66 of the U.S. National Museum, Mr. W. D. Pierce states that he is unable to accept the view that these parasitic insects are modified representatives of the Coleoptera, and accordingly regards them as forming an order by themselves, of which several families, in addition to the typical Stylopidæ, are recognised. In the author's opinion, the Strepsiptera form an order, "on a distinct line of descent from that of the Coleoptera, and nearer the Hymenoptera and Diptera, and as highly specialised as the highest insects in any of the orders." It is remarked that few persons have seen the adult winged males of these insects, although most collectors have marvelled at their portraits in books. The author hopes that the publication of his monograph will lead to a considerable increase in our knowledge of these insects.

To *Spolia Zeylanica* for December, 1909, vol. vi., p. 108, Dr. A. Willey contributes notes on the nest, eggs, and larvæ of the well-known fish *Ophiocephalus striatus*, locally termed in Ceylon the lula, or marral. The most interesting fact in connection with the breeding-habits of this fish is that the eggs float on the surface of the water by their own buoyancy, a feature apparently unique among fresh-water species. In certain other groups the same advantages, namely, proximity to atmospheric air and exposure to sunlight, are partly gained by the suspension of the eggs to plant-stems, their enclosure in floating nests of herbage or foam, or by their deposition in very shallow water. As regards development, the simple ventral flexure of the embryo of Ophiocephalus, the absence of retinal pigment within the egg, and the formation of the pectoral fins after the larva is hatched, are features contrasting with what prevails among many teleosteans. In these the later appearance of the ventral fins is the rule. In the African and American lung-fishes the two pairs of limbs arise simultaneously, but in the Australian Ceratodus the ventrals appear about a month later than the pectorals, much as in Ophiocephalus.

WE heartily welcome another of those meritorious monographs which the Americans are working up so thoroughly with reference to their own fauna. This time it is a "Monograph of the West American Pyramidellid Mollusks," by W. H. Dall and P. Bartsch (Smithsonian Institution, 1909, Bulletin No. 68). Though titularly devoted to the Pacific coast of the U.S.A., this work will be invaluable to all students of marine gastropods on account of its synopsis of genera and sections, forming a complete key to the systematisation of a most difficult family. It matters very little whether we accept the authors' views as to the status of their subgenera and sections or prefer to regard the majority of them as genera. Certainly many, such as Syrnola, Actæopyramis, Mormula, and Menestho, are generally nowadays accorded the higher rank—no doubt in course of time practically all their groups will be so treated. Meanwhile, Messrs. Dall and Bartsch prefer to restrict the number of recent genera, and admit only three of the four to be found in Fischer's "Manuel de Conchyliologie," Eulimella being subordinated to Pyramidella; the latter has altogether twenty-three named subdivisions, Turbonilla has twenty-four, and Odostomia has forty. So far as concerns our British Pyramidellids, the classification coincides mainly with that adopted in the Conchological Society's latest list (*Jour. of Conch.*, 1901). We note, however, several changes. The names Ondina and Pyrgostelis yield in priority to Evalea and Pyrgiscus, and the latter group, typified by the old *Odostomia rufa*, Phil., is transferred—we think more conveniently and correctly—to Turbonilla. A similar transfer is made of *O. fenestrata*, Forbes, and it is placed in a separate subgenus, Tragula. Pyrgulina is reserved for species with a sculpture of impressed spiral lines, and for our species of the *interstincta* type we must substitute the name Parthenina.

THE latest and concluding number of the ninth volume of the *Bulletin du Jardin Impérial botanique*, St. Petersburg, contains a note, by Mr. J. W. Palibin, relating to the distribution of *Adoxa Moschatellina* in the Caucasus and *Ruppia maritima* in south-eastern Siberia, and an article by Mr. A. A. Elenkin in which he presents a survey of certain species of Anabæna, with special reference to a new species, *Anabaena Scheremetiewi*.

A SECOND contribution of notes on Philippine palms, by Dr. O. Beccari, is published in the botanical section (vol. iv., No. 5) of the *Philippine Journal of Science*. The type of a new species, *Normanbya Merrillii*, is provided by a fine palm which has the habit of *Areca catechu*, and yields a nut suitable for chewing; another new species, *Areca macrocarpa*, also bears comparison with the Areca palm on account of its fruit, which is even larger than the betel-nut. Several new species are placed in the genera Livistona, Korthalsia, Heterospathe, and Pinanga; there are also additions to the climbing palms Calamus and Dæmonorops. The same number of the journal contains a first article, by Mr. O. Ames, on Philippine orchids, and a revision of the native Combretaceæ by Mr. E. D. Merrill.

THE useful and general nature of the work carried on in the West Indies under the direction of the Imperial Department of Agriculture is well exemplified in the report presented by the curator of the botanic and experiment stations in the small island of Montserrat. Experiments have been instituted in connection with the important lime-fruit industry to see what results are attained by clean cultivation. The welfare of the peasants receives attention by the provision of help and guidance in cotton cultivation and by the introduction of improved varieties of tannias and cassava, which form a staple article of food. Further, the possibilities of new products are being put to the test in the experimental plots of the wild bay tree *Pimenta acris*, lemon grasses, and *Pilocarpus racemosus*; the two former yield essential oils, while the latter is a source of the drug pilocarpine.

WITH the object of obtaining information regarding the geotropic sensibilities of stalked Basidiomycetes, Dr. F. Knoll carried out a series of experiments with *Coprinus stiriacus*, which he describes in *Sitzungsberichte der kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxviii., part v.). A study of the longitudinal growth shows that there is a growing region at the top of the stipe or fruiting stalk where intercalary growth, due entirely to extension of the separate hyphæ, takes place. The stipes, which in the very earliest stage are ageotropic, become later negatively geotropic. Perception of the stimulus and power of response are manifested by the whole of the growing region. The variation noted in the "reaction-period" is remarkable; while the pileus or cap is young an interval of two hours may elapse between the stimulus and response, but when the spores are ripe this period decreases to a few minutes.

DR. EMIL WERTH contributes an account of the surface features of Kerguelen Island to the *Zeitschrift* of the Berlin Geographical Society. The paper is, to some extent, an abstract of the author's more complete memoir on Kerguelen published in the report of the German South Polar Expedition, 1901–3; it gives an account of the topography of the island, and discusses its relation to volcanic phenomena, past and present glaciation, and rock weathering.

THE December (1909) number of the Bulletin of the American Geographical Society contains an account of some experiments on the artificial formation of deltas, carried out in the laboratory of the geological department of Ohio State University, by Mr. Arthur L. Smith. The experiments produced two general forms of deltas, one with regularly semi-circular outline and one with irregularly lobate outline. It was found that the ultimate form of the first was determined by the maintenance of a constant or increasing stream gradient, and of the second by the decrease of the gradient of the stream. Pronounced cross-bedding was found to occur only in the fore-set layers of the lobate form, and, to a small extent, in all top-set beds. Experiment confirmed the impression, conveyed by an examination of maps of natural deltas, that "fingers" are merely surface features of the delta margin. The shape of a delta is unaffected by the depth of water or irregularities in the bed on which it is formed.

THE Kelvingrove Museum in Glasgow, which belongs to the Glasgow Corporation, contains a valuable collection of minerals, including the Glen collection, purchased in 1896, and the Fleming collection, presented in 1902. The museum is rich in the interesting minerals that have been found in the estuary of the Clyde and at other localities in western Scotland. A useful guide to the minerals in this museum has been written by Mr. P. MacNair, the curator of the natural-history collections (Glasgow: Robert Anderson, 1910, price 3*d*.). More than half the work is taken up with an introduction to mineralogy, which is more technical and advanced in its treatment than corresponding guides issued by other museums. It endeavours to carry the reader farther into the details of crystallography than most visitors to an English museum would care to follow, and the index includes many names of little importance; thus in P are Paulite, Pissophanite, Plinthite, and Protheite. The guide concludes with a brief account of the chief mineral species. It is illustrated by a plate of the interesting calcite pseudomorphs, attributed to Gaylussite, that have been dredged from the Clyde estuary.

STATISTICS of aëronautical patents in recent years are given by Dr. W. A. Dyes in the *Zeitschrift für Luftschiffahrt* for February. The number of complete patents granted in Germany was 73 in 1909, 36 in 1908, 27 in 1907, 14 in 1906. The corresponding numbers of provisional protections were 140, 48, 37, 14. In view of the fact that in Germany applications for patents are not published until the Patent Office has examined their validity, the author gives for comparison the number of applications filed by the English Patent Office in the same years, namely, 776 in 1909, 224 in 1908, 189 in 1907, 43 in 1906, and 19 in 1905.

NO better illustration of German progress in aërial navigation could be found than the long list of local aëronautical societies the official notices of which appear in the German *Zeitschrift für Luftschiffahrt*. In addition to the German Luftschiffer Verband, we have "Vereine für Luftschiffahrt" for the following districts:—Berlin, Central Rhenish, Lower Rhenish (sections at Bonn, Düsseldorf, Krefeld, Essen, Wupperthal), Pomeranian, Bremen, Bitterfeld, Lower Saxon, Brunswick, Hamburg, Saxo-Thuringian (with sections for Thuringian States, Erfurt, and Halle), Breisgau, Frankfurt, Anhalt. The Imperial Aëro Club also occurs in this list, which is based on the February number. We have nothing to correspond with these local societies in England. It must, however, be admitted that the hideous and gruesome illustration of "The Aëronaut's Death" in the January number of the *Deutsche Zeitschrift* is a little out of place in a scientific journal.

DR. F. W. EDRIDGE-GREEN read a paper on colour-blindness at the Royal Society of Arts on February 9. The paper is an excellent and lucid exposition of his well-known views upon the subject, and as such it will well repay perusal. In its general character his theory is one which is attractive to physiologists, but some of his assumptions require more impeccable evidence than is adduced. We may cite as an example the statement that "the decomposition of the visual purple by light chemically stimulates the ends of the cones (very probably through the electricity which is produced)." His strictures of the tests for colour-blindness in common use have at least sufficient foundation to demonstrate the need for their reconsideration as a part of the reformation of the official examinations.

THE November (1909) number of the Bulletin of the Bureau of Standards contains a paper, of nearly fifty pages, on platinum resistance thermometry at high temperatures, by Messrs. C. W. Waidner and G. K. Burgess. They find that temperatures determined on the pure platinum resistance scale standardised at 0°, 100°, and at the boiling point of sulphur, taken as 444·70° C., agree with temperatures on the gas thermometer scale in the interval 0° to 1100° C. within the limits of experimental error of the latter scale. With impure platinum, for which the constant δ of Prof. Callendar's interpolation formula differs from 1·5, the value of δ has to be taken as increasing with temperature by an amount which increases with the degree of impurity before agreement with the gas scale can be secured. With the pure palladium thermometer even this is not sufficient. In neither case is the interpolation formula proposed by Mr. J. D. H. Dickson found suitable. High temperature appears to render the impure platinum purer, possibly by evaporating impurities, as, for example, iridium. The authors consider it desirable that thermometers should be standardised at a fourth point in addition to the three mentioned above, and suggest that the freezing points of metals, even when only commercially pure, are now known with sufficient accuracy, and are so easily reproduced, that they furnish convenient fixed temperatures. They give the following figures for the freezing points:—tin, 231·92°; cadmium, 321·01°; lead, 327·43°; zinc, 419·37°; antimony, 630·71°; aluminium, 658·0°; silver, 960·9°; copper, 1083·0°; the 72 per cent. silver, 28 per cent. copper eutectic, 779·20°.

H.M.S. *Collingwood*, the latest of our Dreadnought battleships, has just completed her official steam, gunnery, and torpedo trials, a brief account of which appears in the *Engineer* for February 11. The *Collingwood* is the sixth ship of her class floated, and was launched from Devonport Dockyard on November 7, 1908. The machinery is of the Parsons turbine type, and there are two complete sets, each set comprising one high-pressure ahead and one high-pressure astern turbine; one low-pressure ahead turbine, in which is incorporated one low-pressure astern turbine and one cruising turbine. The boilers are of the latest improved large-tube Yarrow type, adapted for either coal or oil fuel. During the speed trials the powers specified were easily exceeded, and although the sea was very rough while the battleship was run over the measured mile at Polperro, the designed speed of 21 knots and the specified shaft-horse-power of 24,500 was realised. Other trials included 30-hour runs at 20 and 70 per cent. of the full power, and eight hours at full power. The machinery was constructed by Messrs. R. and W. Hawthorn Leslie and Co., Ltd., the order having been promptly executed despite seven months' lost time during the engineers' strike on the north-east coast.

THE first part of a general description of the engineering and constructional features of the Panama Canal, by Mr. G. W. Goethals, chairman and chief engineer of the Isthmian Canal Commission, appears in *Engineering* for February 11. Among other interesting items, we learn that dynamite is used for blasting, as excessive moisture and water in the holes prevent the use of blasting powder. An average of 1,000,000 lb. of dynamite per month is consumed for the entire work, and the number of accidents has been relatively small, although, owing to the number of men in contracted areas, the casualties have been great. Premature explosions, attributable to concussion during loading, led to the substitution of pine-rammers for those of lignum vitæ. Temperature tests are made prior to loading, as in some cases high temperatures exist in the holes. Unexploded charges, subsequently dug out by steam shovels, led to laying wires direct from electric-lighting plants to the cut in substitution for the ordinary magneto-electric machines operated by hand. The fuses are connected in parallel in lieu of in series, failures often occurring in the latter case, none in the former. No holes are now loaded which cannot be fired the same day, a precaution necessitated by the premature explosion of 22 tons of 45 per cent. dynamite at Bas Obispo, probably owing to some of the nitroglycerine having been liberated and exploded by concussion by a dobie shot in the vicinity. Accidents have occurred during electric storms, and the only possible precaution is now taken by stopping work.

THE evidence given at the Board of Trade inquiry into the Stoat's Nest accident on the London, Brighton and South Coast Railway shows that the left-hand leading wheel of the coach which left the metals had been displaced from its true position on the axle by about one inch. This would be quite sufficient to cause an accident if the wheel had previously shifted, and there is reason to believe that this was the case, as the signalman had seen sparks flying from the bogie frame near this wheel before the accident occurred. Commenting on the evidence, *Engineering* for February 4 points out that in many cases too much reliance is put on the men in charge of the work of pressing wheels on to the axles. A great deal of care is taken by the railway companies, and only experienced men are chosen for this work; but the foremen cannot witness every operation, and there may be a tendency for workmen to pass wheels which have been pressed on at figures barely reaching the required limit. The pressure used in the case of the wheel above mentioned was stated in evidence as sixty tons. It is of interest to note that, at the Horwich works of the Lancashire and Yorkshire Railway, an autographic record is drawn by the press during each operation. Such a record is invaluable as a check on the workmen, and enables the foreman to deal promptly with cases of poor work before the wheels leave the shop. The *Engineer* for February 4, commenting on the accident, says that facing points as now constructed are not dangerous, and that diamond crossings are a source of danger. It is suggested that the accident may have been caused by the wheel, which was wide to gauge, striking the diamond crossing which exists at the place where the accident occurred.

PROF. W. H. HUSSEY contributes to the January Bulletin of the American Mathematical Society tables of Galois fields of order less than 1000.

IN the *Rendiconto* of the Naples Academy (3), xv., 3, 4, Dr. Paolo Rossi discusses the nature of the secondary radiations of X-rays and their dependence on the substance which emits them. A property is referred to, analogous in some respects to Stokes's law of fluorescence.

MESSRS. HOEPLI, of Milan, have issued the fifth and last volume of Brioschi's collected mathematical works, at the price of 30 francs. This volume contains papers contributed to French, German, and English mathematical and scientific journals.

MESSRS. JOHN WHELDON AND CO., of 38 Great Queen Street, Kingsway, London, have issued a classified entomological catalogue, comprising some 1400 books and papers they have on sale. We notice that the list includes some recent purchases and selections from various entomological libraries.

THE ten numbers of the "Bulletin of Miscellaneous Information," issued during 1909 from the Royal Botanic Gardens, Kew, and noticed already from time to time in NATURE, have been published in volume form. Like other Government publications, the book may be obtained, directly or through any bookseller, from Messrs. Wyman and Sons, Ltd., Fetter Lane, London. Its price is 3*s*. 6*d*.

A SECOND edition of Prof. Wilhelm Ostwald's "Grosse Männer" has been published by the Akademische Verlagsgesellschaft of Leipzig. It will be remembered that the first edition of the work was reviewed at length in our issue of July 29, 1909 (vol. lxxxi., p. 121). The price of the volume is 14 marks.

OUR ASTRONOMICAL COLUMN.

COMET 1910*a*.—Reports received from various observers show that at the beginning of this week comet 1910*a* was no longer a striking naked-eye spectacle, and there is little that is new to record regarding it.

Mr. Gustave Gillman sends us a fine drawing showing the comet's position and the extent of its tail as seen by him at Aguilas, Murcia, Spain, on January 27 and 31. For the former date the drawing, which is a large-scale chart of the region of stars wherein the comet was then located, shows, distinctly, the tail extending to ζ Pegasi, making its length more than 20°; but unfortunately the chart is unsuitable for reproduction here.

In *La Nature* for January 29 (No. 1914) M. Lucien Rudaux describes the comet as seen from Paris on January 21 and the succeeding days, and a drawing shows that it had a brilliant nucleus and a well-developed tail, several degrees long, on January 22. A number of observations are also recorded in the *Gazette astronomique* (No. 26), where attention is directed to the fact that if the apparent length of the tail on January 30 were 30°, the actual length was something like 110 million kilometres (68·75 million miles).

A number of drawings and photographs of the comet were shown at the meeting of the Royal Astronomical Society held on February 11. Among other remarkable features were the development of a shorter tail on the southern edge of the main tail, near the head, and the considerable extension of the main tail at its N.E. extremity; this extension curved quite abruptly from the main axis, and reached nearly to γ Pegasi. Mr. Hinks, who showed a number of drawings, directed attention to the fact that the bright nucleus was situated on the extreme inner edge of the head, so that the two branches of the tail appeared to enwrap it completely on the sunward side. The drawings also depicted the zodiacal light, with which the tail appeared to merge, thus forming a magnificent spectacle. Observations are also recorded in No. 6 of the *Comptes rendus* (February 7). MM. Luizet and Guillaume state that on January 29 and 30 the tail was 30° long, and, at a distance of 15° from the nucleus, its breadth was 2°; on January 31 it was distinctly fainter. MM. Javelle, Charlois, and Schaumasse report that on January 25 the nucleus was round and $10''$ in diameter, and two aigrettes, symmetrical with regard to it, were distinctly seen. On February 1 the comet was sensibly fainter, and the aigrettes were no longer visible, whilst a further diminution of brightness was recorded on February 2, and the nucleus was seen to be elongated. M. Borrelly records that on February 3 the side of nucleus nearer the sun was nearly devoid of coma.

THE MAGNETIC STORM OF SEPTEMBER, 1909, AND SOLAR PHENOMENA.—The connection between the magnetic storm of September 25, 1909, and the contemporaneous solar phenomena observed at the Meudon Observatory is discussed by M. Deslandres in a paper which appears in No. 2 of the *Comptes rendus*. A spectroheliogram of the upper hydrogen atmosphere, on September 24 4h. 35m. p.m., shows strong dark *filaments* connected with the spots, the areas of the latter being greatly diminished. At 9h. 3m. a.m. on September 25 these *filaments* had nearly disappeared, and were broken up, and M. Deslandres connects this phenomenon with that of the magnetic storm. A photograph of the "mean layer" of calcium on September 24 shows the eastern spot to be bordered, on its eastern side, with alternate bright and dark filaments, polygonal in form and sharply defined, and a number of similarly shaped flocculi join the two spots. M. Deslandres names this special structure *le réseau chromospherique*, and supposes that it shows the region on the western side of the spot to be in a fairly calm state. Photographs taken for that purpose, on September 24, give no evidence of motion in the line-of-sight, but show the bright vapours above the eastern spot discussed by Dr. Lockyer.

M. Deslandres discusses the several theories as to the solar-terrestrial connection, and shows that the "kathode radiation" theory may explain many of the phenomena. The kathode rays leaving the spot are curved, by the exterior magnetic field of the sun, like the spires of nebulæ, and this may account for the mean "lag" of forty-five hours between the meridian-transit of the spot and the incidence of the magnetic storm. The "whirls" of Prof. Hale thus become the effect, rather than the cause, of the magnetic field, which by M. Deslandres's theory is produced by the corpuscles circulating round the sun with great velocities. The difference between the calcium and hydrogen images is also explained by this theory, for the action of the field would produce different results on atoms of different masses.

THE INTRINSIC LIGHT OF THE SKY.—An interesting method of comparing the intrinsic light of various parts of the sky *inter se* and with stars of known magnitude is described by M. Ch. Fabry in a paper appearing in No. 5 of the *Comptes rendus* (January 31, p. 272).

In the focal plane of an objective of 48 cm. focal length M. Fabry placed a circular diaphragm of variable aperture. Passing through this aperture, the light of the sky fell upon an optical system, of 3·15 cm. focal length and large aperture, which projected an image of the objective on to a photographic plate. Thus the plate registers, as a uniformly illuminated circular area, the whole of the light coming from that part of the sky of which the image is formed behind the diaphragm. In making a determination, two exposures are necessary:—(1) the camera is directed to a star, *e.g.* Polaris, and the diaphragm is closed down so that only the light from the star is allowed to reach the plate; (2) the camera is directed to the region of the sky to be investigated, and the diaphragm opened so that an exposure of equal duration will give an image of equal density to that produced in the first case; a simple calculation then gives the ratio between the intrinsic illumination of the area under consideration and the light of the chosen star.

By this method M. Fabry finds that a square degree of sky, in galactic latitude 30° and near the pole, gives a photographic intensity equal to 0·103 that of Polaris, or 0·92 that of a fifth-magnitude star. The corresponding ratios for an area, of one degree square, between β and γ Cygnus, one of the brightest regions of the Milky Way, are 0·212 and 1·9 respectively. These values differ from those obtained by visual observations, probably because the magnitude of Polaris was taken as 2·62, but if the visual magnitude of the latter is taken, 2·12 on the Harvard scale, the result for 1 square degree of non-galactic sky is 1·46 of a fifth-magnitude star, a value intermediate between those obtained by Newcomb (1·15) and Burns (2·0). As regards the ratio between galactic and non-galactic sky, M. Fabry's results are in accord with the visual observations.

ELLIPTIC ELEMENTS AND AN EPHEMERIS FOR DANIEL'S COMET, 1909*e*.—From observations made at Rome and Nice on 1909 December 8 and 1910 January 2 and 14, Dr. Ebell has calculated elliptic elements for the orbit of Daniel's comet, 1909*e*, which he publishes, with an ephemeris, in No. 4384 of the *Astronomische Nachrichten* (p. 264). The elements give 1909 November 28·91228 (Berlin) as the time of perihelion passage, and 6·403 years as the period, but they are not yet considered final. According to the ephemeris, the comet is now (February 17) 58m. east and 38′ north of δ Aurigæ, and is only about one-fifth as bright as it was on December 8; its daily motion is slightly less than 2m. nearly due east.

PUBLICATIONS OF THE LUND OBSERVATORY, SWEDEN.—From the Lund Observatory, Sweden, we have received three papers, published as *Meddelanden från Lunds Astronomiska Observatorium*. No. 5 (series ii.) is by Prof. Charlier, and discusses the motions of the orbit-planes of satellites in various planetary systems. In No. 6 M. Henrik Block discusses a class of singularities in the problem of *n* bodies, and in No. 40 (first series) Dr. Zinner treats of the secular perturbations in the planetary rotation problem.

IMPROVEMENTS IN RESILIENT WHEELS FOR VEHICLES.

AT a meeting of the Royal Society of Arts held last December, the Hon. R. Clere Parsons gave a brief history of the improvements which had been made from time to time in the wheels of vehicles, which had resulted in the extensive adoption of the pneumatic tyre, and then passed on to describe a spring wheel which possesses practically all the advantages of a pneumatic-tyred wheel without its heavy cost of maintenance and liability to puncture.

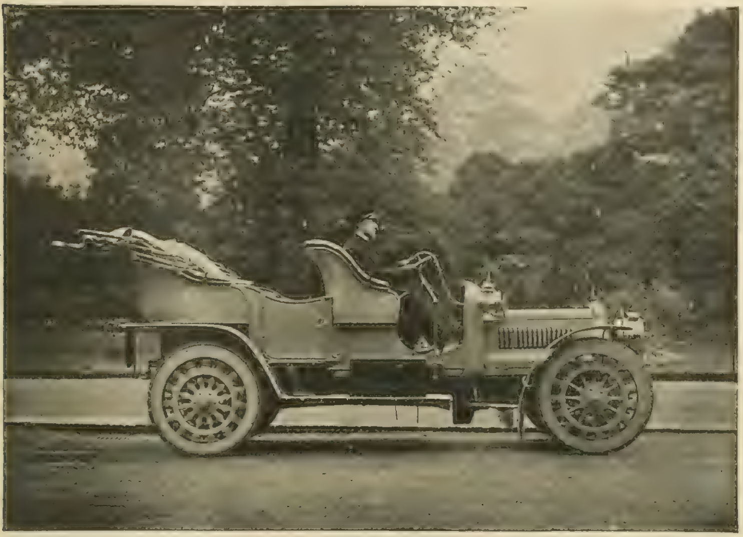

FIG. 1.

The author explained that, before he attempted to design a spring wheel, he had made a careful search through the records of the British Patent Office Library with the view of ascertaining, if possible, why the numerous inventions relating to this question had not been successful. This search led him to believe that if certain principles were adopted, and careful investigations made, there was a prospect of obtaining a trustworthy spring wheel, which as yet had not been produced.

FIG. 3.

The preliminary investigations were made with model wheels 12 inches in diameter, which were tested in the apparatus he described, and in which the effects of the jolts imparted to the wheel were automatically recorded. The result of these investigations indicated that it was possible to substitute spiral steel springs for the air spring of the pneumatic tyre, and at the same time retain practically all its resilient properties.

This special type of wheel, which is known as the "Pan-flex," from its being flexible in all directions, was then carefully designed, and a set fitted to a 28–30 horse-power Daimler touring car, illustrated in Fig. 1, which in running order weighed 2 tons 5 cwt.

The wheel, illustrated in section and elevation in Figs. 2 and 3, consists of a steel channel rim similar to those used for solid rubber tyres, and into which a rubber tyre is inserted. On each side of this channel rim are rivetted annular plates, so as to form an internal channel, in the bottom of which are corrugated transverse projections. To the wheel centre are rigidly fixed spiral springs at regular intervals, which project radially outwards, and to their extremities are attached rubber pads formed with transverse undulations. The diameter of the wheel centre over the pads of the springs being slightly less than that of the channel rim, the wheel centre can be inserted therein, but is not connected in any way with it. The wheel is then complete and ready to be used on a vehicle.

The action of these wheels is simple, and merely consists of the pads on the ends of the spiral springs, as it were, acting as feet, which walk round inside the outer rim, and in turn support the weight of the vehicle. The wheel centre, when the vehicle is travelling along, rotates slightly more rapidly than the outer rim, the advance of the one upon the other being termed the "creep." When any obstacles are passed over, the shocks imparted to the rim of the wheel, which would, if it were a solid one, be transmitted through the axle to the machinery and car body, are absorbed by the rubber pads and springs before they reach the wheel centre. The principle and details of this wheel are quite novel, as has been admitted by the German Patent Office experts previous to granting the patent.

Owing to the rubber caps at the extremities of the spiral springs being capable of deflecting in all directions within certain limits, the friction of the moving parts of the wheel is negligible, and, as a result, practically no heating occurs, consequently the wear and tear is exceedingly small. The spiral springs attached to the wheel centre are designed so that in no case can they be subjected to a strain in any direction whichever approaches their limit of elasticity; consequently, provided no flaw exists in the steel of which they are made, their life should be indefinitely long. If, however, from any cause a spring should break, no inconvenience is felt, as the journey can be completed, and a fresh spring can then be fitted in about five minutes.

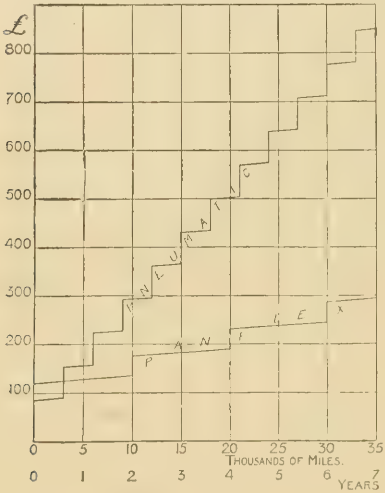

Fig. 4.

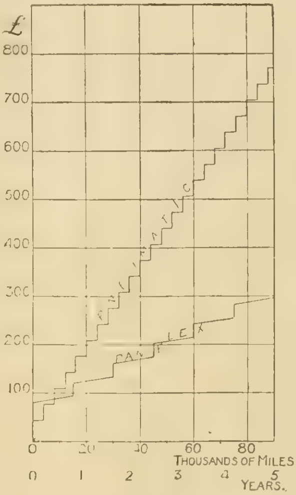

Fig. 5.

The repairs of the "Panflex" wheel merely consist of the renewal of the solid rubber tyre, which can be effected by a coach-builder, and probably an occasional rubber pad or spring, a few of which should be kept in the car. The wheels have been tested on the Daimler car for 4000 miles, and the results indicate that the perishable parts should endure at least 10,000 miles.

These wheels have also undergone very severe tests on a taxi-cab in the streets of London and the suburbs for the last three months with very satisfactory results. The first cost of the "Panflex" wheel is somewhat greater than that of a pneumatic-tyred wheel, but the expenditure on maintenance is much less, as is shown by the diagram exhibited by the author (Figs. 4 and 5), which indicates the saving in maintenance of each car, as regards tyres, by the use of "Panflex" wheels.

In conclusion, the author enumerated the advantages possessed by the "Panflex" wheel, and explained that by its adoption the use of the motor-car could be brought within the reach of persons who are now precluded from availing themselves of it owing to the excessive cost of maintenance of the tyres.

THE SPECTRUM OF THE ZODIACAL LIGHT.

SINCE the time when Cassini published his observations of the Zodiacal Light, in 1682, the question as to the nature and origin of this peculiar phenomenon has been constantly recurring. Visual observers were ever at variance on the subject, some holding the view that the Light was a terrestrial adjunct, others that it was a solar appendage. Visually, the matter is a difficult one to decide, for no optical power may be used because of the lack of contrast between the Light and its background of sky. Photography is similarly placed out of court, but it was expected that the question would be solved by the spectroscope. This expectation has never yet been realised absolutely, but the results recently published (Lick Observatory Bulletin, No. 165) by Dr. Fath clarify matters considerably.

Previous spectroscopic observations have varied on a vital point, viz. the presence or absence of bright radiations in the spectrum, indicating, by their presence, that the Light was self-luminous. Thus some observers found that the spectrum was continuous, others found that its continuity was broken by bright bands, especially the bright aurora line at λ 5571. The argument for the presence of the latter as an inherent element of the spectrum was, however, considerably weakened, if not eliminated, by the observations of Respighi, Vogel, Piazzi-Smyth, and others, who were unable to find the aurora line, when observing the spectrum of the Zodiacal Light, unless it was at the same time to be seen in all parts of the sky. Tacchini, Cacciatore, and Ricca similarly were unable to find it, but agreed that the spectrum was continuous, extending from about λ 5000 to λ 5550, with its maximum intensity at λ 5350; that is to say, the spectrum of the Light resembled the solar spectrum without the absorption lines.

The detection of the dark solar lines is a difficulty inherent to the observation, for the Light is so faint that, to get a visible spectrum, a broad slit is essential, and with a broad slit the comparatively fine absorption lines are lost.

Wright, in 1874, was able to use a narrower slit, and found that the spectrum, with an intensity-curve similar to that of daylight, showed traces of an absorption band in the position of the δ band in the solar spectrum.

Thus it became fairly evident that the Zodiacal Light was reflected sunlight, and the opinion now generally held is that it is reflected by a collection of small meteoritic bodies surrounding the sun; this theory is supported by the observation that a fair percentage of the light is polarised. The recent observation of Prof. Fowler (Nature, vol. lxxxi., p. 396, September 30, 1909), who, during an auroral display, was able to detect the aurora line everywhere, "even in the light reflected by a pocket-handerchief," illustrates the danger of attributing the auroral radiation to the spectrum of the Light, simply because it is seen contemporaneously.

To decide the question of the spectrum of the Light, photographic observations, if possible, were desirable, and, in 1883, Mr. Michie Smith attempted the task of photographing it, but was unsuccessful. Now, however, Dr. Fath has succeeded in obtaining a photograph after exercising a great deal of care and ingenuity in overcoming the numerous difficulties.

The first attempts were made, at the instigation of Prof. Campbell, in 1907 at Mount Hamilton. The spectrograph was especially designed and constructed for this research, and has an aperture of 51 mm.; the focal length of the collimator is 814 mm., and that of the camera is 154 mm. Rigidity, to withstand flexure or distortion over long periods, is the main feature of the frame, which is made of well-seasoned pine 13 mm. thick, shellaced inside and out, and put together with glue and screws. The prism is of light flint having a refractive index of 1·611 for $H\gamma$, and was set for the minimum deviation of this ray; the resulting spectrum is about 2·2 mm. in length from λ 5000 to λ 3900.

In the autumn, when the Zodiacal Light appears in the morning above the eastern horizon, less than one hour before sunrise is available for the exposures, which therefore have to be accumulative. As the altitude of the Lick Observatory is 1283 metres, it was expected that dawn might commence before the zenith distance of the sun was 108°, the usually accepted value, and in the first experiments the exposure was always stopped when the computed zenith distance was 111°; later experiments showed this precaution to be unnecessary.

In August, 1907, an exposure was made, over the period August 8 to 15, totalling 6h. 1m., and in the very faint spectrum secured absorption lines at λ 4300 and λ 3950 were suspected.

A stronger spectrum was obtained in October, 1907, with a total exposure of 11h. 9m., but still the traces of absorption were too faint to permit of any definite conclusions. Another attempt in the autumn of 1908 only served to illustrate the numerous pitfalls awaiting the observer of this evanescent spectrum. Jupiter and Venus were above the horizon, reflecting sunlight, and this so complicated matters that the experiments had to be abandoned.

On his translation to Mount Wilson, Dr. Fath resumed the inquiry, and, by the courtesy of Prof. Campbell, was able to use the same instrument. Elaborate precautions were taken to eliminate any chance of "shift" caused by the vibration or change of temperature of the spectrograph; the instrument was also mounted on an azimuth slide, so that it could be moved in azimuth some 5°, in order to follow the brightest part of the Zodiacal Light. The width of the slit employed was 0·41 mm., and at this width the solar lines H and K are not separated in the spectrum. The exposures extended from 1909 September 12 to September 25 under very favourable conditions, and were always arrested a minute or two before the time calculated for the zenith distance of the sun to be 108°. Careful watch was kept for any abnormal dawn or other phenomena which might vitiate the results, but none was observed.

With a total exposure of 12h. 31m., on a Lumière "Sigma" plate, a spectrum was obtained, under these conditions, which, so far as its small size will allow one to judge, resembles the solar spectrum exactly. Two absorption lines are certainly seen, and a comparison spectrum of daylight shows these to be G and a blend of H and K in the solar spectrum. There are no signs of bright lines on any one of the spectra obtained, and therefore, as Dr. Fath concludes, we seem justified, so far as such small, impure spectra can lend justification, in concluding that the Zodiacal Light is nothing more than reflected sunlight.

To support this conclusion it is, of course, desirable that the work should be continued, using a narrow slit to obtain greater purity of spectrum; but this entails the employment of much quicker plates than are at present available, or a much longer exposure. The latter is at present probably the most feasible plan, but when one remembers that the hours of exposure must be moonless, planetless, and clear, it is obvious that several months would be necessary to complete one such exposure. This means that special precautions to secure the constancy of the spectrograph would be necessary, and Dr. Fath suggests the construction of one with a metal frame, which would be less likely to suffer change than a wooden one, and could be maintained at a fairly constant temperature.

W. E. Rolston.

TECHNICAL EDUCATION IN GERMANY AND THE UNITED KINGDOM.

At the request of Mr. R. Blair, the executive officer of the London County Council Education Committee, a valuable memorandum has been drawn up by Dr. F. Rose on the qualifications of the students trained at the German technical high schools in comparison with those of students at British universities and technical institutions of university rank. This memorandum, with the tabular portion abridged, is subjoined, and it contains facts of great interest and importance. Referring to it, Mr. Blair says:—

"The memorandum shows that one or two broad statements of fact may be made, and these deserve, if they do not demand, attention. First, the schools of the United Kingdom do an immense amount of valuable work in the evening—my own view is that the work is unparalleled. So much further education in the evening is partly due to the fact that a life of earning and independence begins earlier in the United Kingdom than in Germany, and is partly an indication of the inadequacy of the day work in these islands. It is hardly possible—and I have not attempted to do it—to assess this evening work in such a way as to place it side by side with the day work in the United Kingdom in comparing the latter with German day work, and such a comparison would also have required an appreciation of the evening work in Germany. But it has much value. Secondly, taking, as far as one can, comparable institutions, there are 12,000 fully qualified students attending day institutions for the highest technical training in Germany, and only about 3600 in the United Kingdom. The German courses are, speaking generally, longer and the previous preparation better. Further, this great difference in quality and quantity of the work done has existed for more than a generation; and these highly qualified German students have found, and do find, their way into agriculture and industry, because the German people believe in the application of trained intelligence to all forms of national activity."

Dr. Rose's report, in an abridged form, is reprinted below.

Although there is little doubt that the majority of students trained in German technical universities actually take up industrial positions upon leaving, it is impossible to give any detailed information, as no statistics on the subject have been published or are obtainable. Nine years ago I carried out an investigation to show to what an extent the German chemical industries had benefited from the chemical instruction available at universities and technical universities. The proportions still hold good for the present day, although the figures have increased. It was found that there were about 4000 academically trained chemists in the different branches of the chemical industry. The value of the annual production of the chemical industries was estimated at 50,000,000*l*.

The total number of chemists trained in Germany was estimated at the same time at about 7000. It would not be going too far to say that at least four-fifths of the German students actually take up positions in industries and technical work when they leave the technical universities; a very large number of the fully qualified students pass the final diploma examinations.

No account has been taken of the non-fully qualified students, who amount to about 10 or 15 per cent. more. A great many of these students also take up technical positions. In a large number of cases they are the sons or relatives of engineers and manufacturers who, before taking over the family works, wish to study a certain amount of technical science without submitting themselves to the drudgery of an examination.

Although it is almost a matter of impossibility to compare German technical universities with the applied science faculties and departments of English universities and with English polytechnics and technical colleges, an attempt has been made to do so in the tabular statement [here abridged so as to include totals only] given below. The difficulty of comparison arises from the fact that the German technical universities are independent technical institutions, and are organised throughout on a high level and on a uniform scale.

Technical Education in Germany and Great Britain—Educational Year, 1907–8.

Institutions	Number of fully qualified day students (German technical universities). Students taking full courses (English institutions).	Number of non-fully qualified day students (German technical universities).	Number of evening students.	General ages of day students.
GERMANY—				
Ten Technical Universities	11,692	2,299		18 or 19 to 24 and 25 and over Minimum age, 18
UNITED KINGDOM—				
Twenty-three Universities and Colleges of University rank	3,607		16,623	Entrance age, about 16
Eight London Polytechnics, and Technical Schools at Birmingham, Bolton, Leicester, Derby and Salford	461		25,574	Entrance age, about 15

Some of the points of difference may be mentioned. The matriculation for fully qualified students at German technical universities is the completion of the full nine years' secondary-school course at a classical, semi-classical, or modern secondary school. This practically amounts to a B.A. pass degree, say, at Oxford or Cambridge. There are, however, a few exceptions here and there, but they scarcely affect the almost general rule. At English institutions it is in most cases impossible to get any detailed or uniform information on this point, but it is clear that the standard of previous educational qualifications, even at many institutions of university rank, is lower than in Germany. This explains why German students do not commence work at the technical university before eighteen or nineteen, whereas at most English institutions the minimum age limit is sixteen, or there is no limit at all.

The next striking difference is the fact that there are no evening students at German technical universities, whereas in English institutions there are generally more evening students than day students.

Another point of difference is the length of the technical courses. As a rule, these last at least four years in Germany, and most students add one or two additional terms (half-years) to this period. In England the average length of the courses is less in most cases.

With regard to diplomas and degrees, the German procedure is simple and uniform at all the technical universities. The student who has successfully passed through his course of study and passed the necessary examination is awarded a diploma in his special branch. This is sufficient for the needs of the average engineer or manufacturer. If the diploma holder, however, wishes, he can spend one or two years more in research work connected with his particular branch, and can then obtain the degree of doctor of engineering by presenting his thesis and passing a further examination. This arrangement is practically uniform at all the technical universities. English scientific degrees and diplomas, however, are so diverse and numerous that it is almost useless to try and compare them with the German ones.

In addition to the simple diplomas and degrees there are other examinations which must be taken into consideration in dealing with German technical universities. These are the State examinations for State positions in State railways, mines, forests, canals, domains, smelting works; Government building, engineering, and surveying; teaching (secondary schools), post, telegraph, &c., Customs, shipyards, river and coast regulation, pharmacy, food inspection, and so forth. All candidates for these examinations must, of course, be fully qualified students.

The majority of high Government technical officials pass through the classical gymnasia before entering the technical university. The Government examination is, as a rule, more severe than the diploma examination undertaken after a four years' course at some technical universities. The diploma examination is accepted in some parts as equivalent to, or as the first section of, the official State examination for State technical positions. When the numbers of students who pass the diploma and State examinations are compared with the number of students actually at work at a technical university, it will be seen how large a number of German students complete full technical courses and pass the necessary examinations. It should also be mentioned that the majority of German technical universities exact about one year's previous practical work from fully qualified students entering their technical departments. No officials and no persons engaged in the purely commercial aspects of trade may enter as fully qualified or non-fully qualified students.

The German technical universities differ from English institutions, not only in the quality, variety, and length of their technical courses, but in the time devoted to work per day. It does not appear that the whole day is devoted to work at most English institutions. Whilst some work as much as 1000 hours per year, others work less. A minimum of 300 hours has been set up by the Board of Education for statistical purposes. At German technical universities the whole day is devoted to work, and lectures commence at seven in the summer and at eight in the winter, all the remaining time being devoted to work in drawing offices and laboratories.

The final point of difference is that the German technical universities only exist for the purpose of teaching applied science, whereas in England departments for this subject have been grafted upon universities with faculties for science, letters, medicine, law, theology, and so forth. Pure science is, of course, taught at all the older German universities in departments of the philosophical faculties.

No account has been taken in the comparison of the German mono-technical schools—that is to say, technical schools which contain only one, or perhaps two, technical departments, and which admit students about the age of fourteen or sixteen for technical courses lasting from two to four years. Such schools, which may be termed secondary technical schools, provided with fine buildings, full technical equipment, and properly staffed, number about two hundred.

A very large number of technical schools for special branches of trade exist. Such schools have been established for milling, boot-making, tanning, musical instrument making, toy-making, book-making, photography, &c. There are also numerous schools for applied art. It is very difficult to get these schools into line for purposes of comparison. They are of two types, higher and lower; there is a certain amount of overlapping, and the conditions are not uniform. They are in extremely close touch with the industries concerned, and have been founded and developed in their midst. The difference between the technical universities and the best of the technical schools mentioned above may be briefly summed up in the following table of comparison:—

Subject of comparison	At the ten technical universities	At the special engineering schools and other technical schools, with courses in mechanical engineering, building and electrotechnics, &c.
Lowest entrance age	18 years	14 and 16 years
General ages	18 to 25 years	14 or 16 to 30 years
Necessary degree of previous education	The completion of the full courses (9 years) of a gymnasium or full "real" school, making, together with the three years at a preparatory school, a total of about 12 years	Qualification for the one-year military service; (6 years at a secondary school); also completion of the "Volkschule" (elementary school) and a knowledge of mathematics and some years' practical work
Scope and manner of instruction	Advanced and complete application of higher mathematics and mathematical sciences advanced theory and design, facilities for the attendance of lectures in the departments of chemistry, civil engineering, architecture, art, science and literature	A certain measure of instruction complete within certain limits, specially arranged for practical requirements, no higher mathematics, elementary theory and design; no facilities for instruction in other technical departments or in letters, languages, philosophy, &c.
Aim of the instruction	Training of experts, great inventors, high technical State and municipal officials, "captains of industry," owners and managers of great works, professors, secondary teachers, consulting men of science, engineers, architects, chemists, patent agents, &c.	Training of owners and managers of smaller works, foremen, clerks of works, surveyors, minor State and municipal officials, draughtsmen, technical travellers, &c.
Previous period of experience in works	Generally 1 year as minimum, with a tendency to increase	2 to 4 years as minimum, 2 years being exacted almost without exception; very strictly observed
Length of courses ..	4 years in almost all cases, with a tendency to increase	2 to 2½ years, sometimes 1½ years, in rare cases 3 and 3½ years
State and municipal technical appointments open to students who have completed the courses	Higher appointments in the State and municipal technical services	Lower appointments in the State and municipal technical services
Attendance at lectures	No compulsion... ..	Obligatory

Although English universities have been included in the comparison, no mention has been made of the following German institutions of equal or similar rank:—

The twenty older universities (excluding the theological universities of Braunsberg and Münster)	They contain 48,000 students. Of these a large number study chemistry, which is a department of the faculty of philosophy at all German universities
The three agricultural high schools	Same educational qualifications as at the technical and older universities. Exceptions, however, are allowed. Number of students=1402
Agricultural departments	At seven of the older universities and at one technical university
The five veterinary high schools	Same educational qualifications as at the technical and older universities. Number of students =1321
The four forestry academies	Same educational qualifications as at the technical and older universities. Number of students =262
The forestry departments	At three older universities and one technical university
The three mining high schools	Same educational qualifications as at the technical and older universities. Number of students =791
Various	A mining department at Aix Technical University. A veterinary department at Giessen University

The result of this comparison between German and British technical institutions shows that the former are constituted and organised on a higher level. With the possible exception of the Imperial College of Technology and applied science departments at Cambridge, Edinburgh, Glasgow and Victoria Universities, Trinity College, Dublin, and some university colleges, there do not appear to exist in the United Kingdom technical institutions which can be compared with any of the great German technical universities.

Looked at from the basis of the German standard of previous education and practical work, length, extent, and variety of the courses taken, and the number of diplomas granted, it will probably be found that there are insufficient students in the whole country to fill one of the large German technical universities. Here and there a number of students in a few departments come up to the German level. Good technical institutes and departments in England appear to be more on a level with the best technical schools in Germany rather than with the technical universities. Such schools are, for example, the Prussian higher mechanical engineering schools at Dortmund, Elberfeld, Breslau, and Cologne, the trade academy at Chemnitz, the technical school at Cöthen, and several "Technikums." These schools do not admit students before sixteen, require a six years' certificate from a secondary school and proof of two years' practical work, and have a course of at least two years. They are very numerous in Germany.

In England the tendency during the last ten years has been to graft departments for higher applied science upon the older or modern universities. This was done in Germany very many years ago and soon abandoned. For example, engineering was once taught at Giessen University, higher mechanics at Munich University, and technology at Göttingen and other universities. At the beginning of the nineteenth century lectures on technology were given at Heidelberg, which were suitable in every respect for a technical school. Building, mining, metallurgy, forestry, surveying, and other subjects were also taught. At the present time, with few exceptions, applied science and technology generally have gone to the technical universities and institutions of similar rank and to the technical schools. Only comparatively few departments survive, such as forestry, veterinary and agricultural science, which are still taught partly at the older universities, but principally at independent institutions. A very large amount of chemistry, principally pure chemistry, is taught at all German universities. It forms the great exception to the rule, and was taught so far back as the beginning of the seventeenth century. Different countries have, of course, followed different lines of procedure in the development of their higher technical instruction.

The German technical universities are not, strictly speaking, new creations. They have been developed—with one exception—from technical schools, trade schools, &c., founded in the first quarter of the nineteenth century. One of the great reasons for the foundation of these schools was to render Germany independent of the English manufactures and machinery, which, together with English capital and engineers, overran Germany in the first half of the nineteenth century.

The present organisation of English polytechnics represents a stage of development which German technical education passed through about forty years ago, and out of which nine of the ten technical universities have arisen.

There is little doubt that the rapid development of the German technical universities is owing, to a great extent, to their independent position towards the older universities. They do not enter into competition with them, but supplement them by providing a new type of instruction which the older universities, by reason of their environment, traditions, and organisation into the four faculties of law, medicine, theology, and philosophy, cannot give. The same is true of the semi-classical (Realgymnasia) and modern secondary schools (Oberrealschulen). Instead of attempting to graft a large amount of science, modern languages, mathematics, and drawing upon the older classical gymnasia, new secondary schools were created with the same length of courses, but of a semi-classical or completely modern type. All three types remained independent, and have consequently flourished, although the State still favours the classical gymnasia in State appointments and the liberal professions. As the technical universities developed so did the new types of secondary schools from which they receive so many of their students. Coordination between the older and the technical universities has been effected in a simple manner by making the leaving certificate of the secondary schools (the "Maturitas") the standard of matriculation for both types of university, and by putting university and technical university terms on the same footing as regards the length of study for the final examination.

The Emperor William has greatly influenced the rise of the technical universities by his consistent efforts to raise the status of the three (now four) situated in Prussia. He began by suggesting reforms in the secondary-school system, then called the principals of the technical universities into the Prussian Upper House, and finally conferred on the Prussian technical universities the power of granting the degree of Doctor of Engineering. The rest of the Empire followed his example, and thus the ten technical universities have been finally placed upon exactly the same footing as the older universities.

One reason why technical-school students in Germany possess a better educational equipment for their work than in England is owing to the fact that the lower divisions of the secondary schools are filled by students who wish to obtain the one-year military certificate which requires six years' attendance at a secondary school. The high proportion of fully qualified students at the technical universities is due to the fact that no examinations can be passed or higher State or municipal positions obtained without proof of the completion of a nine years' secondary-school course. Another reason why so many students attend the secondary schools and various universities in Germany is due to the lowness of the fees and the cheapness of living. To these reasons may be added the general German tendency to obtain as high a standard of schooling as possible before entering life.

Young men in Germany subject themselves to a laborious general and technical training, amounting after the preparatory school to from ten to fifteen or sixteen years, because the majority of those who complete their studies are generally sure of finding positions. The State and municipalities require large numbers for their various technical services. This partly explains the interest of the State in the quality of the instruction and the uniformity of the organisation of the technical universities. Most manufacturers give the preference to students with diplomas or degrees from the universities or technical schools. This is a result of the intimate advisory relations between manufacturers and the technical universities. Students are also sure of finding positions in the surrounding foreign countries, where large numbers of German "techniker" are to be found in all branches of industry. A further incentive to a longer course of study is found in the fact that, owing to the system of marriage dowries in Germany, young men with a technical diploma or degree are able to marry as soon as they obtain a position, even with a very small initial salary.

German students receive very little direct pecuniary assistance. Scholarships on the liberal English scale are practically unknown. There are a few modest "stipendia," and very poor students, upon production of the necessary proof, are allowed to study free and refund the amount of their fees later when they are in a position to do so.

Higher education of all types in Germany has been promoted by two further factors. First, by decentralisation so far as the Empire is concerned, as the various States of which the German Confederation is composed act independently in educational matters, and are constantly competing with one another in the development of their educational resources. Secondly, by the fact that almost all higher education is under direct State control, thereby rendering uniformity of organisation and coordination between institutions more easy.

Finally, it should be borne in mind that the German population exceeds the population of the United Kingdom by about eighteen or nineteen millions.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Rev. E. A. Woodruffe-Peacock will deliver a lecture at the Botany School on Friday, February 18, at 5.0 p.m., on "A Special Method of Recording the Distribution of Plants." The lecture will be open to all interested in the subject.

Prof. W. Bateson, the Hon. N. C. Rothschild, and Mr. H. Scott, Inceptor in Arts, have been nominated to represent the University at the International Congress of Entomology to be held at Brussels in August, 1910.

Sir J. Larmor has been nominated a member of the board of electors to the professorship of chemistry, Sir Robert Ball to that of the Plumian professorship of astronomy, and Dr. Glaisher a member of the same board; Prof. A. Robinson and Prof. A. Keith have been nominated members of the board of electors to the professorship of anatomy, Dr. Darwin to that of the professorship of botany, Prof. W. W. Watts to that of the Woodwardian professorship of geology, Mr. A. Hutchinson to the same board, Prof. H. B. Dixon to that of the Jacksonian professorship of natural and experimental philosophy, Prof. A. R. Cushny to that of the Downing professorship of medicine, Dr. Hugo Müller to that of the professorship of mineralogy, Dr. R. T. Glazebrook to that of the Cavendish professorship of experimental physics, Dr. W. N. Shaw to that of the professorship of mechanism and applied mechanics, Prof. F. Gotch to that of the professorship of physiology, Sir W. W. Cheyne, Bart., and Mr. C. T. Dent to that of the professorship of surgery, Prof. J. Lorrain Smith to that of the professorship of pathology, and Mr. E. Gardner, M.P., to that of the professorship of agriculture.

London.—In memory of the late Dr. Ludwig Mond's scientific eminence and his generous benefaction of 3000*l.* towards the building of the Institute of Physiology at University College, the college committee has resolved to name the biochemistry research department of the institute "The Ludwig Mond Biochemistry Research Laboratory." The committee will shortly proceed to elect a Crewdson-Benington research student. The studentship, of the value of 50*l.*, tenable for one year in the biometric research laboratory of the college, is for the promotion of research in anthropometry and craniology in relation to evolution. Candidates should send their applications, together with any statement of qualifications that they desire to submit, not later than March 1 to the secretary of University College, Gower Street, W.C., who will furnish particulars of the studentship.

The degree of D.Sc. has been granted to Mr. W. B. Tuck, an internal student, of University College, for a thesis entitled "The Constitution of Hydroxyazo-compounds," and other contributions.

A scheme for the constitution of a board of the faculty of medicine has been approved.

Syllabuses have been approved in geology for intermediate and final pass B.A. examinations for external students. Practical work is provided for in both syllabuses; that for the intermediate examination includes the interpretation of weather charts, and at the final examination candidates must give evidence of adequate instruction in the field.

Prof. A. W. Crossley, F.R.S., has been elected dean of the faculty of science in succession to Prof. J. M. Thomson, F.R.S., resigned.

Dr. E. C. Seaton and Mr. W. H. Maxwell have been appointed Chadwick lecturers in hygiene and municipal engineering for the current session.

Convocation has approved the proposals for the establishment of a University of London Club.

At the South-western Polytechnic Institute, Chelsea, on March 11, Sir William H. White, K.C.B., F.R.S., will present prizes and certificates to students of the evening classes and day college.

The twelfth annual dinner of the Central Technical College Old Students' Association was held on Saturday, February 12, at the Trocadero Restaurant, Mr. H. A. Humphrey being in the chair. Among the guests of the evening were Sir Philip Magnus, M.P., who, in proposing the toast of the association, mentioned the great progress the Central Technical College has made and the invaluable training received there. Prof. W. J. Pope, F.R.S., was elected president for 1910.

An interesting address to the junior members of the architect's profession was given on January 31 by Mr. Ernest George, president of the Royal Institute of British Architects, and has been printed in the *Builder* for February 5. Mr. George offered much valuable advice to the student; earnest application is necessary, and a thorough education in science and art, as well as in wider fields of knowledge. There will be no time for idling; an architect must recognise that he is a man of business, with grave responsibilities to his client, and must cultivate methodical habits and exactness. The art of public speaking should be part of the architect's equipment; he may thus often contribute profitably to discussions.

The scheme for a London pageant which was before the public some time ago is now merged into a larger scheme of a Festival of Empire, to be held at the Crystal Palace this summer in the months of May, June, and July. The London pageant will form part of the scheme of the festival of empire. The council of the festival has invited the cooperation of the University Extension Board of the University of London in arranging courses of lectures preparatory to the pageant. The Board has accordingly arranged a course, to be given by Mr. Kenneth H. Vickers, on the history of London, arranged specially in view of the pageant of London to be held at the Crystal Palace as a part of the festival of empire. This course will be given in the London Day Training College on Thursday evenings at 8 o'clock, beginning February 17, when Sir R. Melvill Beachcroft, chairman of the London County Council, will take the chair. It is hoped that further courses of this kind will be arranged in different parts of London later in the year.

Of recent years the system of furthering scientific research most in vogue has consisted in the foundation of studentships or fellowships tenable at some university, for which recently graduated students of that or other universities are eligible. While this movement has undoubtedly led to the performance of a large amount of research in experimental science, and has, in this respect, been an unqualified success, it is a matter of common experience that the holders of these endowments have not, as a rule, reached a sufficiently mature age or acquired sufficient experience to initiate and develop original work in pure science. Indeed, it is not uncommon to find a successful research student baffled by a comparatively simple problem in mathematical analysis. In an article on "An Empire University" in the *Standard* for February 7, Dr. Waller, F.R.S., proposes a scheme which would obviate this difficulty. He suggests a class of appointment the holder of which should devote half his time to, and receive half his stipend from, teaching, the other half of his time being given to research, for which the corresponding remuneration should take the form of a fellowship. It is pointed out that this combination of teaching and research could not fail to have a beneficial effect in infusing an element of originality and individuality into the teaching. Dr. Waller's proposal might further have the advantage of improving the position of the existing underpaid assistant lecturers in our university colleges. Many of these at the present time turn out really excellent original work in addition to teaching, in return for a stipend which compares unfavourably with the awards made to research students for advanced study alone. There certainly appears to be a loss of efficiency in the existing system.

The annual meeting of the Association of Technical Institutions was held at the Skinners' Hall, London, on February 11 and 12. Dr. R. T. Glazebrook, F.R.S., president of the association, delivered his address, and dealt with the questions, What should be the aims of those teachers whose work lies mainly in the technical institutions of the country, and what should be their position in the scheme of education which is being gradually evolved? He pointed out that in Germany the great technical institutions have developed almost independently of the old universities, and asked, Are we to look forward to the growth of technical universities in each town arising naturally out of the technical colleges, but independent of and at the same time rivals of the existing universities? The answer Dr. Glazebrook thinks should be in the negative, with possibly one or two exceptions. It would be suicidal to suggest that in Manchester, Birmingham, Leeds, or Liverpool there should be two degree-giving bodies, one concerned with arts and pure science and the other with applied science. Modern universities, he said, will do for us what technical high schools have done for Germany. Speaking of London, Dr. Glazebrook said we may take it that the Imperial College of Science and Technology will in time become the technical university of London, whether as a part of London University or as a new university. On the second day of the meeting a general discussion took place upon the examination of evening students by the Board of Education, the City and Guilds Institute, the Royal Society of Arts, and the London Chamber of Commerce. Speaking on behalf of the Board of Education, Mr. C. A. Buckmaster said the Board is at present considering the whole subject of examinations, and will be glad to receive any information which the association can put before it. It realises the immense difficulties connected with the long period of the examinations, and will be prepared to do what it can to diminish the inconvenience. With regard to the Whitworth examinations, the Board of Education has to administer the will of Sir Joseph Whitworth, and though slight modifications of the scheme are possible, it would require an Act of Parliament to enable the Board to put it wholly into the melting-pot so that it may come out in a different form. After further discussion, a resolution was passed instructing the council to consider the subject of examinations in all its bearings.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 10.—Sir Archibald Geikie, K.C.B., president, in the chair.—Dr. C. **Chree**: Some phenomena of magnetic disturbances at Kew. A recent paper ("Phil. Trans.," A, vol. ccviii., p. 205) discussed the diurnal inequality of Kew magnetic declination derived from 209 of the most highly disturbed days of the eleven years 1890 to 1900. The present paper discusses the corresponding phenomena for the same days in the other magnetic elements. It is shown that the irregular changes which form the most obvious feature of magnetic storms are accompanied by large *regular* diurnal changes, which are specially striking in the vertical force. In this element the disturbed days referred to above gave a regular diurnal inequality, the range of which in the average month of the year was about four times that given by the Astronomer Royal's "quiet" days. The influence of the hour of the day on the character of the disturbance is visible even on casual inspection of the vertical force curves. When disturbances lasting only a few hours occur in the late afternoon, there is almost invariably a rise in the force, whereas when they occur in the early morning there is a fall. Besides dealing with the analysis of the diurnal inequalities derived from the disturbed day curves, the paper discusses some new phenomena observed in the a-periodic changes of the magnetic elements.—R. B. **Sangster**: A novel phenomenon in the diurnal inequality of terrestrial magnetism at certain stations. The mean diurnal inequality at Greenwich for epoch 1900–6, at Falmouth, 1903–7, and at Pawlowsk (Russia), 1873–85, is dealt with so as to exhibit the inequality in the plane of the astronomical meridian. It is then shown that the component of the force parallel to the earth's axis has little, or no, variation during the hours from noon to about 5 p.m. There is, however, considerable simultaneous variation in the declination and in the horizontal and vertical forces. The winter months invariably showed a shorter duration of the feature, and, generally, a larger diurnal range produced a more exact and lengthened exhibition of the phenomenon. The phenomenon was found to exist whether "quiet" days or "all" days were dealt with, and, while long periods naturally furnished smoother curves, the feature was also prominent in cases where the mean of only five "quiet" days in a single month was employed.—Prof. P. V. **Bevan**: The absorption spectra of vapours of the alkali metals. The paper gives an account of the absorption spectra of vapours of the metals potassium, rubidium, and cæsium. Prof. R. W. Wood has shown that the absorption spectrum of sodium vapour has for its most striking feature the lines of the principal series. The same series lines for the metals of this communication appear in the absorption spectra. The author has measured the wave-lengths of these lines so that now 24 potassium lines, 25 rubidium lines, and 19 cæsium lines are known of the principal series. Of these, 15 are new in the case of potassium, 21 in the case of rubidium, and 12 in the case of cæsium. In the cases of rubidium and cæsium, the metals themselves were not available, but by heating the chlorides with sodium or potassium, enough vapour was obtained to show the absorption spectrum quite definitely. These lines, with the lines measured by Wood for sodium, give good data for testing various formulæ that have been suggested for representing the series lines. None of the suggested formulæ tested give values representing the series within the limits of experimental error. In particular, the quantity of Rydberg's formula N_0, or of the modified Rydberg formula of Ritz, is shown not to be constant. One of the most interesting facts arising out of the investigation is that none of the lines of the associated series appear in these absorption spectra. Channeled space spectra appear which are analogous to the similar spectra for sodium vapour. Further interesting facts noted are in regard to the effect of mixtures of vapours. Some lines or bands appear in spectra of mixtures which are apparently unconnected with the spectra of either constituent. This was specially evident in the case of cæsium and sodium; a set of bands appeared at about W.L. 3000–3500 which do not appear in the sodium spectrum, nor in the mixture of potassium and cæsium spectrum. Other interesting phenomena appear as the density of the vapour is increased in the widening of the lines and the appearance of satellites connected with the lines of the series. The vapour of lithium has not yet been successfully investigated, as it attacks the material of all tubes hitherto tried.—Prof. C. H. **Lees**: The shapes of the isogeotherms under mountain ranges in radio-active districts. The author shows that for mountain ranges of many different forms of section, the shapes of the isogeotherms may be accurately determined in cases in which the heat conductivity and radio-activity of the materials of the range may be taken as constants. Curves showing the isogeotherms in three typical cases are given, and it is shown that some of the statements generally made with respect to them are not correct.—F. B. **Pidduck**: The propagation of a disturbance in a fluid under gravity. The paper relates to the determination of the motion set up in a heavy incompressible fluid of uniform depth by a limited initial disturbance; the generally accepted solution in terms of a definite integral represents the disturbance as being propagated instantaneously, although the velocities of the simple harmonic wave-trains of which the solution is built up are all finite. In the paper this solution is transformed into a series-solution analogous to that given by Cauchy and Poisson for infinite depth. In the more general problem of one-dimensional motions in dispersive media the integral solution may represent the disturbance as either being limited at any time by an advancing wave-front, or as being propagated instantaneously. A method, based on the examination of the convergence of the definite integral, is given for deciding between these conditions. An investigation is given of the propagation of waves over a slightly compressible heavy fluid. Solutions of the Cauchy-Poisson type give motions which such a fluid can execute; but these are not due to limited initial disturbances, as they imply a diffused initial condensation. The corresponding result for incompressible fluids is that solutions of the type in question imply a diffused unequilibrated distribution of pressure on release from the initial state.—Dr. A. H. **Gibson**: The flow of water through pipes and passages having converging or diverging boundaries. A series of twenty-five pipes, all having the same initial and final area, but having different angles of convergence or divergence, were examined. Some of these pipes were circular in section; others square; others rectangular. The following are the main conclusions:—(*a*) In a circular pipe with uniformly diverging boundaries, the total loss of head attains its minimum value with an angle of divergence θ of about 5° 30′. Owing to the comparatively large effect of friction in a pipe having a small value of θ, the value giving the minimum loss of head will be somewhat less in pipes larger than those examined, which had a larger diameter of 3 inches and a smaller diameter of 1·5 inches. (In large pipes of the type used in the Venturi meter, experiment shows that this value is about 5° 6′.) As θ is increased the loss of head, expressed as a percentage of $(v_1-v_2)^2/2g$, increases very rapidly from its minimum value of about 13·5 per cent. to a maximum of about 121 per cent. when $\theta=63°$, afterwards diminishing to about 102 per cent. as θ is increased up to 180° (a sudden enlargement of section). (*b*) The effect of making the pipe trumpet-shaped so as to give a rate of change of velocity uniform per unit length of the pipe may in some cases be to increase, in other cases to reduce, the loss of head. In the only case tried in the circular pipes the loss in the trumpet-shaped pipe was 23·5 per cent., as against 17·3 per cent. in a straight taper pipe of the same length, and having θ equal to 10°. In the case of a rectangular pipe, however, boundaries curved to give respectively uniform retardation in time and length ($dv/dt=$ const.) and ($dv/dx=$const.), showed that the loss, as compared with that in the corresponding straight-taper pipe ($\theta=20°$), was reduced respectively by 5·3 per cent. and 12·1 per cent. Further experiments are desirable to determine precisely the form of curve giving least loss of head. (*c*) The loss of head in a pipe of square section is greater—at the least 20 per cent. greater—than in a circular diverging pipe of the same length and same initial and final area, while the minimum loss is obtained when the angle between opposite faces of the pipe is approximately 4°. (*d*) A change in the shape, as opposed to the area, of the cross-section of a pipe leads to considerable loss of head. Thus, by changing the section of a pipe from that of a square of 2·66 inches side to a rectangle 1·33 inches by 5·32 inches in a length of 9·94 inches, a loss of head equal to 0·484 $v^2/2g$ was experienced. (*e*) Where a rectangular pipe has one pair of sides parallel and the second pair uniformly diverging, the loss of head is much greater than in a circular pipe having the same length and the same initial and final areas. The minimum loss is obtained with θ about 11°. (*f*) The critical velocity of flow in a circular pipe with uniformly converging boundaries is much greater than in a parallel pipe of the same mean diameter. The critical velocity increases rapidly with the angle of convergence, its lower value, at 57·5° F. in the experimental pipes (from 3 inches to 1·5 inches diameter), being as follows at the point where the diameter is $2\frac{1}{4}$ inches:—

θ	5°	7½°	10°	15
C.V. (ft. per second)	2·7 ...	3·4 ...	4·3 ...	5·7

The lower critical velocity in a parallel pipe of the same mean diameter is 0·13 foot per second at this temperature.—R. **Rossi**: The effect of pressure upon arc spectra:—Titanium. The work is on the range from λ4000 to λ4600, examined with the $21\frac{1}{2}$ ft. concave grating spectrograph of the Manchester University Physical Laboratory, which gives on the photographic plate a dispersion of 1·3 Ångström units per millimetre. The arc was formed between a carbon pole and a graphite tube filled with titanium carbide. The pressures at which the photographs were taken were 15, 30, 50, and 100 atmospheres. The broadening, reversal, displacement, and changes of relative intensity of fifty-two lines were studied. All lines were found to broaden out with an increase of pressure, the amount and type of broadening being different for different lines. Several lines were found to reverse under pressure, some symmetrically and some asymmetrically. All lines were found to be displaced towards the red end of the spectrum, the displacement being a linear function of the pressure within the limits of accuracy of experiment. The value of the displacement varies for different lines, and the unreversed lines cannot be grouped into sets giving the same displacement. The reversed lines, however, with the exception of one, can be formed into two groups, their mean displacements being very nearly in the ratio 3 : 5. The mean displacement per atmosphere of all the titanium lines studied is found to be 0·003652 Ångström unit. The limited number of lines studied, both in this work and by other workers on the Zeeman effect, do not enable one to obtain any relation between the pressure displacement and magnetic separation. The relative intensity in nearly all lines is altered by pressure, and a list is given of the lines which are thus enhanced or weakened.—Sir James **Dewar** and Dr. H. O. **Jones**: The change of carbon disulphide into a gaseous product condensable and explosive near the temperature of liquid air.

Physical Society, January 21.—Dr. C. Chree, F.R.S., president, in the chair.—R. E. **Baynes**: Saturation specific heats, &c., with van der Waals's and Clausius's characteristics. By use of a special variable, exact expressions may be found with van der Waals's characteristic for the specific heats **s**, **s**′ of saturated liquid and vapour and for all other magnitudes connected with the state of saturation, and if $\mathbf{k}$ denotes the isometric specific heat, which is constant or a function of the temperature only, (i) $\mathbf{s}-\mathbf{k}$ is always positive, increasing from R to ∞ as the reduced temperature τ rises from 0 to 1; (ii) $\mathbf{k}-\mathbf{s}'$ is always positive, having a minimum value 4·96 R when $\tau=0{\cdot}72$, and being ∞ when τ is either 0 or 1; (iii) inversion in the sign of $\mathbf{s}'$ can thus occur when $\mathbf{k}/R>4{\cdot}96$ or $\kappa=1+R/\mathbf{k}<1{\cdot}202$, so that, on the assumption that $\mathbf{k}/R=N+\frac{1}{2}$ for an N-atomic gas, inversion can occur only if the gas has at least *five* atoms in its molecule; (iv) the latent heat of vaporisation increases continuously from 0 to its largest value (27/8)RT as τ falls from 1 to 0, T being the absolute critical temperature; (v) the work of vaporisation has a maximum value 0·55 RT when $\tau=0{\cdot}70$. Clausius's characteristic similarly treated gives widely different results:—(i) while $\mathbf{s}-\mathbf{k}$ is always positive, it is ∞ when τ is either 0 or 1, having a minimum value 15·3 R for $\tau=0{\cdot}83$; (ii) $\mathbf{k}-\mathbf{s}'$ is always positive, is ∞ when τ is either 0 or 1, and has a minimum value 11·36 R for $\tau=0{\cdot}81$; (iii) inversion in the sign of $\mathbf{s}'$ can thus only occur if $\mathbf{k}/R>11{\cdot}36$ or $\kappa<1{\cdot}088$, or, on the above assumption, if there are at least *eleven* atoms in the molecule; (iv) the latent heat of vaporisation increases continuously from 0 to ∞ as τ falls from 1 to 0; (v) the work of vaporisation has a maximum value 0·69 RT when $\tau=0{\cdot}77$. The contrast between these results is especially marked for $\mathbf{s}-\mathbf{k}$ and the latent heat.—Prof. **Thornton**: The polarisation of dielectrics in a steady field of force. Experiments on the polarisation of dielectric ellipsoids and cylinders suspended in a steady electric field. From measurements of the field-intensity, the dimensions of the ellipsoids, and the frequency of torsional swings with and without the field, the dielectric constant can be found from time to time. The longitudinal component of polarisation reached a higher value than previously recorded, and was found to be independent of the intensity of the field inside the ellipsoid and to be quasi-elastic in type. Quartz, fused and crystalline, flint-glass, amber, sulphur, ebonite, rubber, gutta-percha, paraffin-wax, resin, and sealing-wax were examined. From the rate of increase of the dielectric constant the specific resistance of these was found by considering the change of polarisation to be equivalent to a current. The rate of depolarisation when the field was reversed was the same as that of polarisation, and uniform for several hours. The cause of this and for the independence of the field-intensity may be looked for in the continued separation of molecular charge by the attraction of the opposite charges on adjacent molecules induced by the application of the field. From a comparison of these results and those in alternating fields, the variation of the dielectric constants with frequency can be anticipated.—A. **Campbell**: The use of mutual inductometers. In the use of mutual inductometers, the use of a balancing coil in one arm of the bridge causes considerable loss of sensitivity. With an equal-arm bridge this difficulty is overcome by putting the halves of the secondary circuit in adjacent arms of the bridge. The auxiliary balancing coil is dispensed with, and the usual formula is applicable. The measurement of effective resistance, which is, in general, more troublesome than that of self-inductance, was discussed. The effective resistance determines the total power spent by an alternating current in a conductor, and is important in telephonic and other high-frequency work. When measured by a self-inductance bridge, large errors may be introduced by the small residual inductances of the ratio arms. The analogous formulas for mutual inductance bridges, which indicate that the inductances of the ratio arms must be accurately proportional to their resistances if errors are to be avoided, are here worked out. A null method in iron testing analogous to Max Wien's self-inductance method is described. The ring to be tested is wound with primary and secondary coils. The magnetising current, I_1, is passed through the primary coil, the primary circuit of a mutual inductometer, and a slide-wire resistance. The detecting instrument is put across a circuit consisting of the secondaries of the ring and the inductometer in opposition, and a part, Q, of the slide-wire resistance. By adjusting Q and the reading M of the inductometer a balance is obtained, in which case the power lost in the ring is equal to $QI_1^2\times N_1/N_2$, where N_1 and N_2 are the numbers of turns in the windings of the ring. The method is applicable to the testing of current transformers.

Mineralogical Society, January 25.—Prof. W. J. Lewis, F.R.S., president, in the chair.—Dr. S. J. **Shand**: A group of minerals formed by the combustion of pyritous shales in Midlothian. At the Emily coal-pit, Arniston, as the result of the slow combustion of a heap of shaly refuse, which became spontaneously ignited, presumably owing to the evolution of heat caused by the atmospheric oxidation of pyrites, a number of uncommon mineral species have been formed, of which five have been recognised, viz. native sulphur, sal-ammoniac, tschermigite, mascagnite, and a possibly new species, aluminium sulphate.—Prof. W. J. **Lewis**: A crystal-holder for measuring large specimens. For this purpose a clamp of convenient form and with various adjustments has been designed and made by Mr. Pye.—T. **Crook**: Some observations on pleochroism. The phenomena of pleochroism displayed by plates of coloured minerals when examined in ordinary light were treated in a general way for both parallel and convergent rays, and the factors upon which they depend were discussed.—L. J. **Spencer**: Notes on the weight of the "Cullinan" diamond, and on the value of the carat-weight. Varying statements of the weight of the "Cullinan" diamond, in its original, uncut form have been published, but from a comparison of the carat-weights against which it was weighed in 1905 it is concluded that the correct weight was 621·2 grams, or $3025\frac{3}{4}$ English carats of 205·304 milligrams (as defined by the Standards Department of the Board of Trade in 1889). Other values are, however, given for the English carat and for the carat in other countries, and the average value has decreased, on the whole, in course of time. The carat-weight had its origin in the use as weights of seeds of *Ceratonia siliqua*, which weigh approximately a carat. The existing confusion would be obviated by the general adoption of the metric carat of 200 milligrams (one-fifth of a gram) recently recommended by the International Committee of Weights and Measures (NATURE, 1908, vol. lxxii., p. 611).—Dr. G. T. **Prior**: A basalt from Rathjordan, Co. Limerick. Specimens of basalt from Rathjordan in the Allport collection in the British Museum show in thin slices under the microscope round sections of isotropic material containing central and marginal inclusions, and thus resembling small leucites. The rock is very similar, mineralogically and chemically, to leucite-basalts from Bohemia, but contains only a small fractional percentage of potash. This fact, combined with observations of the refractive indices, leads to the conclusion that the isotropic material is mainly analcite, and not leucite.—Dr. G. F. H. **Smith** and Dr. G. T. **Prior**: A fluo-arsenate from the Indian manganese deposits. A crystallographical and chemical examination made of the green arsenate from Kajlidongri, Jhábua State, mentioned in Mr. Fermor's monograph on the manganese-ore deposits of India (Rec. Geol. Surv. India, 1908), led to the following results:—composition, $(MgF)CaAsO_4$; specific gravity, 3·768; hardness, $3\frac{1}{2}$; colour, apple- to brownish-green; monoclinic, $a:b:c=0{\cdot}7485:1:0{\cdot}8453$, $\beta=120°\ 50'$; forms present, (010), (110), (111), $(\bar{1}31)$, (311), $(\bar{1}12)$, $(\bar{1}52)$; good cleavage parallel to $(\bar{1}01)$, and partings parallel to (110), $(\bar{1}02)$, (331); twin plane, (100); refractive indices, 1·640, 1·660, 1·666; acute bisectrix nearly perpendicular to $(\bar{1}01)$, and axial plane at right angles to the plane of symmetry, but no horizontal dispersion was noticed; $2E=105°$ approximately, with negative birefringence. The material is probably identical with tilasite, which was first described by Sjögren in 1905 from the manganese deposits of Långban, Sweden.—H. E. **Clarke** and Prof. H. L. **Bowman**: The composition of a stone from the meteoric shower which fell at Dokáchi, Bengal, on October 22, 1903. The small crusted stone examined, weighing 17·8 grams, shows chondritic structure, and belongs to the class Ci of Tschermak. The chief constituent minerals are bronzite (37·9 per cent.), olivine (37·7 per cent.), nickel-iron (18·5 per cent.), troilite (4·1 per cent.).—Dr. G. F. H. **Smith** exhibited cut and rough specimens of synthetical sapphire recently produced by Prof. Verneuil, oxides of iron and titanium being the colouring agents.

Geological Society, January 26.—Prof. W. J. Sollas, F.R.S., president, in the chair.—Dr. A. S. **Woodward**: A skull of Megalosaurus from the Great Oolite of Minchinhampton. The specimen was discovered and prepared by Mr. F. Lewis Bradley, and shows, for the first time, the skull of Megalosaurus. It agrees closely with the megaloaurian skulls of other genera already discovered in the sic and Cretaceous of North America, and resembles atosaurus in possessing a bony horn-core on the nose. As in the jaws of Megalosaurus previously known, the premaxilla of the new specimen bears four teeth; but these teeth are so different from those of the typical *M. bucklandi* of the same horizon that they prove the Minchinhampton fossil to belong to a distinct species.—A. M. **Finlayson**: Problems of ore-deposition in the lead and zinc veins of Great Britain. Chemical analyses show traces of lead and zinc in several of the rock-formations of Britain, but the ores of the veins are concluded to be derived, not from the country-rock, but from deeper sources, probably in the first place by magmatic segregation. They were transported in the deeper zones by "juvenile" waters, in which fluorine was an important constituent, while in the upper zones, especially in limestone districts, underground waters of meteoric origin have played a large part. The vein-solutions carried (1) alkaline sulphides, which held the sulphides of the metals in solution, and (2) alkaline and earthy carbonates. The presence of the latter is indicated by the alteration of the wall-rock, which shows a concentration of potash, lime, and carbon dioxide, and a leaching of soda, magnesia, oxides of iron, and silica. In limestones, however, the chief effects of solution on wall-rock were concentration of silica and magnesia. Ore-deposition has persisted over a vertical range of 5000 to 6000 feet, of which more than one-half has been shorn off by denudation. The effects of secondary processes have been exerted to depths of more than 600 feet.—J. W. **Jackson**: The vertebrate fauna found in the cave-earth at Dog Holes, Warton Crag (Lancashire). The remains described in this communication were obtained during the systematic investigation by the author of a cave on Warton Crag (west Lancashire) in 1909. The cave, known as Dog Holes, is situated on the western side of Warton Crag, and opens on a sloping "pavement" of limestone. It owes its origin to the erosion of a series of master-joints in the Carboniferous Limestone. The specimens were derived from the cave-earth below the surface-soil in one of the chambers of the cave. They comprise a large series of small vertebrates, including rodents, Insectivores, amphibians, birds, &c. Among the rodents are some interesting forms, the chief of which are the Arctic and Norwegian lemmings and the northern vole. A large series of non-marine Mollusca was found along with these remains, one species being of particular interest, namely, *Pyramidula ruderata*, only known in this country by its fossil remains in Pleistocene deposits. The Pleistocene age of the remains is fully discussed, as well as their possible mode of origin through a former swallow-hole. In many respects the cave and its contents bear a striking resemblance to the famous Ightham fissures.

Zoological Society, February 1.—Prof. E. A. Minchin, vice-president, in the chair.—The Hon. P. A. **Methuen**: A collection of fresh-water Crustacea from the Transvaal. An account of some Entomostraca collected from Lake Chrissie and other pans or lakes in the Carolina district, which is high veldt country lying near the borders of Swaziland. The paper also gave a short description of the "lie" of the lake, and notes on the geology of the district and the composition of the water.—Dr. J. **Pearson**: Holothurioidea from the Kerimba Archipelago, Portuguese East Africa, and from the Mergui Archipelago, Lower Burma. The collection from the Kerimba Archipelago contained twenty-one species, all of which had been previously described. In this paper it is proposed to establish a new genus for the inclusion of *Colochirus violaceus*, Théel. The collection from the Mergui Archipelago called for no special comment, none of the fourteen species being new.—Dr. G. S. **Brady**: A revision of the British species of Ostracoda belonging to the subfamilies Candoninæ and Herpetocyphridinæ. The paper was a synopsis intended to show our present knowledge of the families referred to, describing briefly the known British species. Some few new genera and species, and others already described by foreign authors but not previously recognised as British, were dealt with.—F. E. **Beddard**: The anatomy of *Hippopotamus amphibius*.

Royal Anthropological Institute, February 8.—Mr. J. Gray, treasurer, in the chair.—A. L. **Lewis**: Some dolmens of peculiar types in France and elsewhere. The author described several *allées couvertes* in the department of the Oise, in France, which have at one end an open portico or shrine with a round hole 18 inches in diameter opening into the *allée*. He then sought to find the monuments most nearly resembling them, which appeared to be some of those in the provinces of Bohuslan and Vestergothland, in Sweden, described by Dr. Oscar Montelius. The "Giants' Graves" in Sardinia, recorded ninety years ago by Count de la Marmora, and quite recently by Dr. Duncan Mackenzie, had some points in common with them, but they also had quite special features of their own, and it did not appear to the author that there was any real connection between the dolmens of the Oise and those of Sweden or Sardinia, as several other kinds of dolmens seemed to bar the way between them. His general conclusion was that the building of dolmens was not confined to one race and the building of circles to another, nor that there was any one race which originated or diffused both, but rather that megalithic construction was a phase of culture through which many races have passed and which was developed in different ways, not only by separate races, but also, in very restricted areas, by different tribes, without regard to any racial differences or connections between them.—Dr. J. S. **Holden**: The existence of a Palæolithic bed beneath the glacial Boulder-clay in south-west Suffolk. The implements were discovered in a well sinking at a depth of 100 feet in a seam of unrolled gravels beneath the blue Boulder-clay. The finding of these rude implements *in situ* beneath the glacial Boulder-clays is of considerable importance, as they are evidence of the existence of man on this old land surface probably long before the beginning of the Glacial period. In the discussion, although doubt was expressed as to the artificial character of the implements by some of the speakers, the general opinion was that they were of human workmanship.

Mathematical Society, February 10.—Sir W. D. Niven, president, in the chair.—H. W. **Richmond**: Note on double-sixes of lines.—Dr. H. F. **Baker**: Notes on the theory of functions. (1) On a certain logical principle; (2) on the establishment of the order of a doubly periodic function; (3) two queries.—Prof. H. **Lamb**: The diffraction of a solitary wave.

EDINBURGH.

Royal Society, January 10.—Dr. James Burgess, vice-president, in the chair.—E. M. **Wedderburn**: Current measurements in Loch Garry. The measurements were made with an Ekman current meter. The general conclusions drawn from the Loch Ness observations were confirmed. At the end of the lake the currents were not very uniform, but some very steady currents were observed at the centre. The return current was strongest just above the temperature discontinuity, and at the bottom indications were obtained of currents in the same direction as the wind. The currents were most uniform with moderate and steady winds. In stormy weather they were very variable, both in direction and in velocity.—John **McWhan**: Observations on some spark-gap phenomena. The paper described a number of curious effects produced by and on sheets of dielectrics interposed in various ways in the path of the electric discharge in air. Many of these depended on the fact that the electrodes were not in the line of the spark. In some the dielectric was perforated, in others it was driven in a definite direction with or without rotation, as the case might be, and in other cases the accompanying luminous effects with the brush discharge were very remarkable. The phenomena could not be co-ordinated on any of the ordinarily accepted theories.—Dr. G. A. **Carse** and D. **MacOwan**: Earth-air electric current and atmospheric potential gradient near Edinburgh. The observations were made with Wilson's portable electrometer. The values of the earth-air current in the town were found to be about one-tenth of those got by

Mr. Wilson at Peebles; at the Blackford Hill, just outside the city on the south, the value was about three times as great as in the city, and at an intermediate station intermediate values were found.—Dr. J. S. **Thomson**: Alcyonaria from the Cape of Good Hope, part i. The paper contained a description of thirteen species obtained off the shore in depths varying from 10 to 70 fathoms. Six were new to science, and one new genus was recorded.—Prof. J. T. **Morrison**: Notes on proposed meteorological instruments. The one was a self-recording anemometer capable of giving at once the north-south and east-west components of the wind's velocity. This was to be accomplished by use of a sphere which, by means of appropriate gearing, was kept rotating at a rate proportional to the wind velocity, while its horizontal axis of rotation was so connected to the vane as to point along the direction of the wind. Two small discs, equidistant from and respectively north and east of the vertical line through the centre of the sphere and pressed against the lower surface, would then rotate with the sphere and thus record the two components. The other instrument was a modified air thermometer, which could be set by comparison with a contiguous Six's thermometer in such a way that the reading gave at once the barometric pressure. The instrument was portable, and was intended to take the place of the aneroid, one of the most untrustworthy of all instruments used by travellers.

January 24.—Prof. Ewart, vice-president, in the chair.—Dr. Williamina **Abel**: The development of the autonomic nervous mechanism in the alimentary canal of the bird. In the wall of the alimentary canal there are various nerve plexuses and ganglia arranged in two layers, the function of which is to control and regulate the movements of the intestine. Are these nerve structures developed *in situ* or are they outgrowths from the central nervous system? From the point of view of physiological experiment the balance of evidence is in favour of the first view, the work of Bayliss, Starling, Langley, Elliot and others pointing to the possession of peculiar properties which separate these intestinal plexuses off fundamentally from the nerve elements of the central nervous system. The evidence afforded by histological examination of the developing embryo is, however, for the most part in favour of the second view. His, senior, Onodi, and His, junior, all support the outgrowth theory as a result of investigations made by them on the relationship of the visceral nerve supply to the central nervous system. It seemed desirable to repeat the investigations with the use of the modification of the silver nitrate staining method introduced by Ramon y Cajal. The material used was embryonic chicks varying in age from two to seven days' incubation. The work was carried out in the physiological laboratory of Glasgow University, and led to the conclusion that the autonomic nerve mechanism in the alimentary canal is formed as an outgrowth from the central nervous system. This view, which receives the support of different histologists, would suggest that the peculiar properties to the autonomic nerve mechanism of the alimentary canal were secondary in development to that of the cells.—J. J. **Simpson**: A new species of Cactogorgia. This specimen, which differed in certain specific characters from other known forms of Alcyonaria, was one of the collection in the Royal Scottish Museum. Unfortunately, there was no label of any kind or mention of the locality where it had been found.—Dr. J. **Oliver**: The stimulatory action of the oosperm in the uterus.—Dr. J. **Brownlee**: The significance of the correlation coefficients applied to Mendelian distributions. This paper gave an account of the manner in which the values of the correlation coefficient varied according to the method of calculation when populations of parent and offspring obtained on the Mendelian hypothesis were examined, and it was shown that in cases of dominance the four-fold division method gave higher correlation values than the product method. The effect of different forms of assortive mating on the correlation coefficient was also shown, and from one form of assortive mating a series of hereditary correlation coefficients were obtained identical with those found from observation. The effect of selective mating was considered, and the forms of selective mating which raised were distinguished from those which lowered the correlation coefficient. The correlation coefficient from parent to offspring when three races mix instead of two was also investigated, and the values of the coefficient in this case found to be considerably higher. Fraternal correlation was found to be considerably increased by assortive mating, and in certain cases by selective mating, while in the case of a mixture of more than two races further increase took place. These theoretical deductions were illustrated by cases of inheritance of colour in animals.

PARIS.

Academy of Sciences, February 7.—M. Emile Picard in the chair.—D. **Gernez**: A means of restoring phosphorescent properties to the sulphides of the alkaline earths. A sulphide of strontium, which immediately after its preparation phosphoresced brilliantly, slowly lost this property on exposure to air, but regained its phosphorescence on heating to redness in a current of hydrogen. This regeneration of the phosphorescence also takes place with barium sulphide.—M. van der Waals was elected a foreign associate.—M. **Luizet** and J. **Guillaume**: Observations of the Innes comet (1910*a*) made at the Observatory of Lyons. Results for January 26, 29, 30, and 31.—MM. **Javelle, Charlois,** and **Schaumasse**: The comet 1910*a*. Observations made at Nice. Data given for January 25, 26, 27, February 1, 2, 3. The comet has a round, well-defined nucleus 10″ in diameter.—M. **Borrelly**: Observations of the comet 1910*a* made at the Observatory of Marseilles with the comet finder of 16 cm. aperture. Data given for January 25, 26, 27, 29, 30, and February 1 and 3.—M. **Coggia**: Observations of the comet 1910*a* made at the Observatory of Marseilles with the Eichens equatorial of 26 cm. aperture. Results for January 25, 26, 29, 30, and February 1 and 3.—MM. **Claude, Ferrié,** and **Driencourt**: The comparison of chronometers or clocks at a distance by the method of coincidences by means of radio-telegraphic signals. Details are given of the mode of transmission of the signals. The method was tested between the observatories of Paris and Montsouris. The errors are less than 0·01 second. Further comparisons will be carried out between Paris and Brest as soon as the damage done to the apparatus at the Eiffel Tower by the floods has been repaired.—A. **Demoulin**: The K systems and congruences.—Johannes **Mollerup**: A remark on integral equations of the first species.—Nicolas **Kryloff**: Developments following hypergeometric polynomials.—Michel **Plancherel**: The representation of an arbitrary function by a definite integral.—Richard **Birkeland**: Some irregular integrals of linear differential equations.—A. **Étéve**: Autorotation. An explanation of an experiment due to M. Riaboutschinsky.—C. E. **Guye** and S. **Ratnovsky**: The variation of the inertia of the electron as a function of the velocity in the kathode rays and on the principle of relativity. The experimental results are compared in parallel columns with the figures calculated from the hypotheses of Lorentz and with those calculated from Abraham's formula. The deviations from the Lorentz are about 1 to 2 per cent., 16 being positive and 11 negative. The divergences from the Abraham formula amount to nearly 4 per cent., 26 being positive and 1 negative. Hence it is clear that the Lorentz formula alone is compatible with the experimental results.—G. A. **Hemsalech** and C. **de Watteville**: The high-temperature flame spectrum of iron. The temperature used was that of the oxyacetylene blow-pipe. The spectrum is very nearly the same as that obtained with the oxyhydrogen blow-pipe, except that the intensity of all the lines is so much increased that an exposure of ten minutes is sufficient to give the image of a well-developed spectrum.—M. **Guilleminot**: The radiochroism of organic bodies towards the α, β, and γ rays of radium and the X-rays.—Louis **Dunoyer**: The emission of electric charges by the alkaline metals. A repetition of an experiment due to J. J. Thomson on the emission of negative corpuscles by rubidium. The author thinks that the assumption of the spontaneous explosion of some atoms, analogous to the destruction of radio-active atoms, is not necessary for the explanation of the facts observed.—Louis **Nomblot**: The reduction of the nitroso derivatives of acetyl- and benzoylhydrazobenzene. Various attempts to produce triazane derivatives by the reduction of these compounds with hydrazine hydrate, aluminium amalgam, and zinc powder were unsuccessful.—A. **Trillat**: Disinfection by incomplete combustion.—F. **Bordas** and M. **Touplain**: Contribution to the study of the reactions due to the colloidal state of milk. The authors think that their results demonstrate the uselessness of assuming the intervention of anæroxydases, catalases, &c., to explain the phenomena of the decomposition of hydrogen peroxide in milk.—MM. **Maurain** and **Warcollier**: The action of the ultra-violet rays on wine in course of fermentation. It is shown that the sterilisation of white wine is easier than cider.—J. **Chevalier**: The influence of culture on the amount of alkaloids in some Solanaceæ. In the cultivation of belladonna the addition of phosphatic or potash manures did not cause any addition to the alkaloid percentage; the amount of the latter is considerably increased, however, by the use of nitrogenous manures, a mixture of nitrates and farmyard manure giving the best results.—M. **Hegyi**: Some observations on the black scab of the potato. This disease, which has caused great damage to the potato crops in Hungary and Germany, has been attributed to *Bacillus phytophthorus*, propagated by infected tubercles. The author's observations have led to the conclusion that the disease is not propagated by the tubercles, but is due to the bacteria of the soil penetrating through lesions into the interior of the stem.—M. **Doyon**: The formation in the liver of an anti-coagulating substance under the influence of an alkaloid.—A. **Rosenstiehl**: The consequences of Young's theory. Chromatic construction in space.—Louis **Roule**: Fishes of the family of Nemichthyides.—E. **Vasticar**: The structure of the tectoria.—H. **Vincent**: The experimental bases of anti-typhoid vaccination.—H. **Carré**: The etiology of intestinal congestion in the horse.—L. **Cayeux**: The limestone algæ of the Girvanella group, and the formation of ooliths.

DIARY OF SOCIETIES.

THURSDAY, February 17.

Royal Society, at 4.30.—Phosphorescence produced by α- and β-Rays: E. Marsden.—Theory of the Luminosity produced in Certain Substances by α-Rays: Prof. E. Rutherford, F.R.S.—(*a*) The Scattering of the α-Particles by Matter; (*b*) The Ionisation produced by an α-Particle. Part II.: Connection between Ionisation and Absorption: Dr. H. Geiger.—The Influence of Pressure on the Boiling Points of Metals: H. C. Greenwood.—On the Viscosities of the Gases of the Argon Group: A. O. Rankine.

Royal Institution, at 3.—Illumination, Natural and Artificial (Experimentally Illustrated): Prof. S. P Thompson, F.R.S.

Linnean Society, at 8.—The Plum-moths of the Seychelles Expedition: T. B. Fletcher, R.N.—Die von Herrn Hugh Scott, auf den Seychellen gesammelten Embiidinen, Coniopterygiden und Hemerobiideen: Dr. G. Enderlein.—Die Termiten der Seychellen-Region: Dr. Nils Hohngreen.—On the Land and Amphibious Decapoda of Aldabra: L. A. Borradaile.

Royal Society of Arts, at 4.30.—The Bombay Housing Question: G. O. W. Dunn

Institution of Mining and Metallurgy, at 8.

Royal Geographical Society, at 5.—Waves in Water, Sand, and Snow: Dr. Vaughan Cornish.

Royal Anthropological Institute, at 5.—Head Hunters in Assam: T. C. Hodson.

Institution of Electrical Engineers, at 8.—Electric Clocks: F. Hope-Jones.

FRIDAY, February 18.

Royal Institution, at 9.—Halley's Comet: Prof. H. H. Turner, F.R.S.

Institution of Mechanical Engineers, at 8.—Annual General Meeting.—*Further discussion*: Ninth Report to the Alloys Research Committee: On the Properties of some Alloys of Copper, Aluminium, and Manganese (with an Appendix on the Corrosion of Alloys of Copper and Aluminium when Exposed to the Sea): Dr. W. Rosenhain and F. C. A. H. Lantsberry.

Institution of Civil Engineers, at 8.—Irrigation Works: Sir R. Hanbury Brown, K.C.M.G.

SATURDAY, February 19.

Royal Institution, at 3.—Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

MONDAY, February 21.

Royal Geographical Society, at 8.30.—Explorations in and around Lake Chad: Captain J. Tilho.

Royal Society of Arts, at 8.—The Petrol Motor: Prof. W. Watson, F.R.S.

Victoria Institute, at 4.30.—Arianism in its Bearing on Modern Questions: Prof. H. M. Gwatkin.

TUESDAY, February 22.

Royal Institution, at 3.—The Emotions and their Expression: Prof. F. W. Mott, F.R.S.

Royal Anthropological Institute, at 8.15.—Notes on the Northern Albanians: Miss M Edith Durham.

Institution of Civil Engineers, at 8.—The Hudson River Tunnels of the Hudson and Manhattan Railroad Company: C. M. Jacobs.

WEDNESDAY, February 23.

Geological Society, at 8.—Metamorphism around the Ross of Mull Granite: T. O. Bosworth.

Royal Society of Arts, at 8.—Oxy-acetylene Welding: H. S. Smith.

British Astronomical Association, at 5.

Royal Meteorological Society (in the Physical Laboratory of the University of Manchester), at 5.—Investigation of the Electrical State of the Upper Atmosphere made at the Howard Estate Observatory, Glossop: Dr. W. Makower, A. J. Makower, and Miss M. White.—Results of the Hourly Registering-balloon Ascents from Manchester, June 2 and 3, 1909: W. A. Harwood.—Line Squalls and Associated Phenomena: R. G. K. Lempfert and R. Corless.

THURSDAY, February 24.

Royal Society, at 4.30.—*Probable Papers*: Colour-blindness and the Trichromatic Theory of Colour Vision: Sir William Abney, K.C.B., F.R.S.—Contributions to the Biochemistry of Growth: (*a*) The Total Nitrogen Metabolism of Rats bearing Malignant New Growths; (*b*) Distribution of Nitrogenous Substances in Tumour and Somatic Tissue: W. Cramer and H Pringle.—The Alcoholic Ferment of Yeast Juice: Part V., The Function of Phosphates in Alcoholic Fermentation: Dr. A. Harden, F.R.S., and W. J. Young.—And other Papers.

Royal Institution, at 3.—Illumination, Natural and Artificial: Prof. S. P. Thompson, F.R.S.

Institution of Electrical Engineers, at 8.

FRIDAY, February 25.

Royal Institution, at 9.—Colours of Sea and Sky: Lord Rayleigh, O.M., F.R.S.

Physical Society, at 5.—Telephone Circuits: Prof. J. Perry, F.R.S.—On the Laws regarding the Direction of Thermo-electric Currents enunciated by M. Thomas: Prof. C. H. Lees, F.R.S.—A New Method of Determining Thermal Conductivity: H. R. Nettleton.

Institution of Civil Engineers, at 8.—Irrigation Works: Sir R. Hanbury Brown, K.C.M.G.

SATURDAY, February 26.

Royal Institution, at 3. Electric Waves and the Electromagnetic Theory of Light: Sir J. J. Thomson, F.R.S.

A TEXT-BOOK OF BOTANY.

Warming-Johansen, Lehrbuch der algemeinen Botanik. Herausgegeben von Dr. E. Meinecke. Zweiter Theil (Schluss). Pp. iv+481–668. (Berlin: Gebrüder Bornträger, 1909.) Price 4.80 marks.

PROF. WARMING'S book, the concluding part of which has recently been issued, will be received with interest, whilst at the same time it cannot escape some criticism. But in the latter connection the circumstances of its publication must, in fairness to the author, be kept in mind. The first part was three years in the press, and even after its appearance an interval of two years elapsed before the second and final part was issued. Botanical thought has moved rapidly during the last decade, and any text-book must naturally suffer when produced under conditions so disadvantageous as those under which Prof. Warming's book has laboured.

The earlier chapters of the first volume contain a morphological treatment of the plant on interesting lines, the ecological factors due to physical environment, &c., being kept well in sight. Many excellent figures are given, and examples are drawn from plants which are not always utilised in these matters as they might be in modern works. Some topics strike us as having been somewhat inadequately discussed, however, and especially that of phyllotaxis. If this subject is to be introduced at all (and it can hardly be omitted in a treatise such as this) one looks for more than a somewhat perfunctory account of the Braun-Schimper views.

The chapter on abstract morphology appears to us rather to miss fire—either it is too long, or it is not long, or philosophical, enough. The cell also is treated perhaps somewhat dogmatically. This may be difficult to avoid in a treatise which, while aiming at being comprehensive, is limited in size. In any event, however, there is no excuse for the introduction of the old and long discredited figure of the lily cell showing large centrosomes. This figure is the more surprising since the author himself avows his disbelief in the centrosomes as there reproduced! The section dealing with the tissue systems is good; we would willingly have seen it enlarged. Many interesting observations are worked in with the general mass of information, and the whole is admirably handled and illustrated. The general classification of the tissue systems follows that employed by Haberlandt in his well-known treatise.

The structure of the wood is well described and figured, though the difficulties (*e.g.* sliding growth) presented by the differentiation of the elements are passed over. This is, however, evidently in keeping with the main plan which the author has kept before him, of making his book chiefly informational, rather than to introduce a discussion of the many doubtful and difficult problems. Similarly, the question as to the mode of formation of annual rings only occupies a few lines.

The latter part of the first volume contains an account of the physiology of nutrition, transpiration, growth, and irritability. The matter is connected up with the life of plants in the open, and although there may be differences of opinion as to the validity of the author's views on some matters—*e.g.* the ascent of sap—everyone will probably admit that the subject-matter is treated in an interesting way. This especially applies to the section on the regulation of functions.

The first part ends in the middle of an account of the reproductive structures, and this is continued in the second and final instalment of the work. The treatment is too short to enable anything like justice to be done to this important subject, the Florideæ, for example, being dismissed with rather less than a page of print.

The morphological discussion undoubtedly loses much on account of the omission of illustrations drawn from palæontological evidence; and, again, we find a figure (476) of the germination of the pollen grain of Lilium showing centrosomes, while in the legend we read that "the centrosomes are to be neglected." Why use such a figure when there are others to choose from? Or, better still, why not draw a new one?

The chapter dealing with the life-history of the plant and its relation to external conditions is, as one would anticipate, one of the most interesting in the book, and the pages devoted to the consideration of the occurrence and significance of rhythm and of the resting periods of plants will be found to be very suggestive. Rhythm is indeed one of the most striking of physiological phenomena, and the resting period is one of its remarkable phases.

The volume ends with a brief account of the general questions which centre around heredity, variability, and such like problems. The examples are well chosen, and the student will find the discussion helpful.

The book as a whole compares well with many text-books that have appeared in recent years. It also shares some of their inevitable defects. The subject is really too large to be treated within limits of space which twenty years ago were reasonably adequate. An author who attempts to do so is bound to incur adverse criticism, and we have given, perhaps, a somewhat candid expression of our own opinion of the present work in what has gone before. But we do not intend to convey the impression that Prof. Warming has not ably discharged his task, so far as it was possible for anyone to do it.

The book is really stimulating in many ways; indeed, any work by Prof. Warming, who has done so much to initiate ecological work, could not fail in this respect; and so we leave it, passing lightly over what may be looked on as unavoidable imperfections, and congratulating the author on the chapters of his work in which he has achieved unquestioned success.

J. B. F

THE AGRICULTURE OF MODERN EGYPT.

Text-Book of Egyptian Agriculture. Edited by G. P. Foaden and F. Fletcher. Vol. i. Pp. 320. (Cairo: Ministry of Education, 1908.) Price 30 P.T.

THE introduction of agricultural schools and colleges into countries where agriculture has hitherto been nothing more than a tradition must inevitably lead to the production of a number of text-books specially written for particular countries. Although the same broad principles hold everywhere, the factors coming into play are so numerous that the student cannot apply the principles to particular cases until he has had considerable experience in the analysis of agricultural problems. He must, indeed, learn his principles through the local practices, and no matter how sound a book may be, its usefulness is very limited unless it is well furnished with local applications.

The present volume is the first attempt yet made to teach agricultural science through Egyptian illustrations. The volume before us deals with soils, irrigation, land reclamation and manures. A second volume is promised dealing with crops, fungoid and insect pests, and animals. The services of several contributors have been enlisted.

The general result is distinctly satisfactory; the student gets the kind of information he wants, and probably forms a more intelligent appreciation of the principles of his subject than would otherwise be possible. The book is also useful to the non-technical reader interested in Egypt, because of its accounts of the land-development methods now in process of application.

The opening chapter deals with the Egyptian climate and its effect on crops. Then follows a long chapter on the composition and properties of soil in relation to plants, and afterwards we turn to the more special Egyptian part, which is very interesting. The valley of the Nile is bounded by high land said to be incapable of cultivation; the population is essentially agricultural and shows no sign of emigrating southwards to the Soudan; in consequence, the agriculture of Egypt must develop on intensive lines. The area of land is being increased by reclaiming the lakes and their margins and the waste lands of the interior; it is calculated that another 25 per cent. can still be added to the present cultivatable area. Drainage, reclamation, and irrigation of land are therefore described in considerable detail. The water is either pumped or syphoned out from the lake; then the canals and drains are completed, and next the land is washed with the Nile flood to remove salt, of which all but the last 1 or 2 per cent. can be readily removed. Finally, the land is levelled to facilitate irrigation; this is done by means of a scoop, but is very expensive and laborious. It is then ready for cultivation, but as it may contain 1 or 2 per cent. of salt a small millet ("dineba"), useful for fodder, and capable of withstanding salt, may be grown as a first crop, or, if the conditions are more favourable, rice. In the Wady Tumilat a reed known as samar, and used for making mats, &c., is largely cultivated for this purpose. If dineba or rice grow successfully, the second stage may be entered upon with a crop of berseem, or Egyptian clover, which enriches the land in nitrogen and organic matter, two defects from which it suffers. The process is now complete, and cotton or other crops can be taken; the land has not, however, attained its maximum productiveness, but will go on improving for several years. Bad spots must be improved by alterations in drainage, extra washing, or ploughing.

The composition of the solid matter brought down by the Nile naturally receives attention. On an average it contains 0·13 per cent. of nitrogen while the river is in flood, but five or six times as much in the months of low Nile. Speaking generally, Egyptian soils are said to be deficient in nitrogen and also in phosphoric acid, but only occasionally in potash.

The general chapter on soils reveals a defect from which this type of book must suffer. The subject-matter is in places rather out of date, while statements are often made on very slender evidence. Far too much is made of an alleged acid excretion from the plant root; there is really no evidence that anything except carbonic acid is given off. Sulphate of ammonia is incorrectly said to be of no value as manure unless nitrifying organisms are present. Salts are stated to diffuse upwards in the soil even when there is no upward movement of the soil water. The existence in the soil is assumed of waste products of plant life injurious to other plants. Other instances might be quoted. These things can, of course, be put right in subsequent editions, but it is in the direction of keeping the strictly general and scientific matter up to date that writers of local text-books will find their chief difficulty.

THE BINNENTHAL.

La Vallée de Binn (Valais). Étude géographique, géologique, mineralogique, et pittoresque. By Léon Desbuissons. Pp. viii+328 and map. (Lausanne: Georges Bridel et Cie., 1909.) Price 10 francs.

THE Binnenthal, a valley in the south of Switzerland on the Italian border, is little known to the many English people who yearly visit that delightful country. It was "discovered" more than twenty-five years ago by a well-known member of the Alpine Club. He loved the quiet and beauty of this valley, as well as the numerous walks and climbs; when his friends asked him to describe it, his answer was, "There is no glacier there and no alpine glow," and, thanks to his reply, the valley has remained unspoilt by the tourist crowd.

For the last ten years the Binnenthal has attracted the special attention of mineralogists on account of the discovery of more than twelve minerals new to science; some of these consist only of a few minute crystals of which there is not yet sufficient material for a chemical analysis.

M. Desbuisson has produced, with the able assistance of numerous men of science and writers, a very interesting account of the natural and local history of the Binnenthal. This book contains a number of beautiful photographs and drawings by the author; especially worthy of mention are the photographs of "Les Gorges des Twingen" and "Le Hamlau de Z'Binnen"; there are also excellent maps, in the execution of which his position as Géographe du Ministre des Affaires étrangères has given him exceptional facility.

The first chapter describes the streams and waterfalls, the contour of the surrounding mountains, the valleys and passes, taking the more important mountains in separate groups. Chapter ii. deals with the geology of the district, and is accompanied with some sections after Dr. Schardt and a geological map after Prof. Schmidt and Dr. Preiswerk. Until recently this district has presented one of the most difficult geological problems in Switzerland, but through the study of the arrangement of the rocks exposed in piercing Monte Leone for the Simplon tunnel, MM. Schardt, Schmidt, and Preiswerk have been enabled to elucidate the geological difficulties of the Binnenthal district. To geologists visiting this valley, this chapter and the numerous references to other authors will be of much assistance, even though M. Desbuisson's deductions may not be entirely accepted.

Chapter iii. is devoted to mineralogy, a subject occupying nearly half the book. The number of different minerals found in this district amounts to more than eighty; of these, fourteen are new minerals found in the Lengenbach quarry. The author gives a short description of the different minerals, with references to original papers. The arrangement is puzzling, as he mixes the carbonates, the sulphates, and the oxides together, and writes calcite $CaCO^3$, siderite CO^3Fe, anhydrite SO^4Ca, barytes $BaSO^4$. There are ten plates of various crystals photographed by the author from specimens in the collections of M. Gustave Seligmann, of Coblenz, the École des Mines, Paris, and from the author's own collection. They may be interesting as records of these specimens, but are of little assistance in helping the collector to recognise these rare minerals. Photographs of minerals are seldom satisfactory, except those in Miers's "Mineralogy," which have been outlined and shaded by Miss Miers. Chapter iv. describes the history and customs of the people. This is written in a very interesting manner, and gives a vivid picture of the development of the valley and the lives of the inhabitants. References are made to that very interesting book of M. Charles Biermann, "Vallée de Conches," and to Dr. Bernouilli's account of the prehistoric remains found when enlarging the hotel at Binn. The rings, brooches, and other objects found in the graves are now preserved in a case in the hotel.

Slight mention is made of the animals and birds of the district, but a complete list of the plants is given in an appendix by Dr. A. Binz; we should like also to have seen an equally complete list of the rare and beautiful butterflies and beetles for which the Binnenthal is remarkable, and which so greatly attract the notice of entomologists. The last chapter gives a clear and accurate description of the walks and climbs, but of the latter many are too difficult and hazardous to be attempted without a guide. We may conclude by saying that this artistically written and carefully compiled account will add much to the interest and enjoyment of those visiting the Binnenthal, and we think that an abridged edition in English would be most acceptable to the English and American visitors.

HYDRAULICS.

Text-book on Hydraulics. By G. E. Russell. Pp. vii+183. (New York: Henry Holt and Co., 1909.) Price 2.50 dollars.

WITH the advent of electricity, and in the first flush of its successful application to many purposes hitherto served by water, it was claimed that the days of hydraulic power were numbered, and that ere long the study of hydraulics would lose all except merely academical interest. That such has not proved to be the case is now a matter of common knowledge, and, in fact, the rivalry between the two motive agencies can only be said to have been stimulating alike to both of them. In regard to their industrial application, there are wide and distinct fields of usefulness for each, and, rightly understood, the two sciences are collaterally valuable, and even, to some degree, complementary. Altogether, far from the relegation of hydraulics to a background of obscurity and neglect, there has, of late years, been a decided recrudescence of interest in the science which engaged the attention of philosophers more than 2000 years ago, and has been dignified by the researches of Archimedes, Bernouilli and Pascal.

Many are the text-books which have been written for the benefit of the student, and the majority of them approach the subject from a practical point of view, or, at any rate, give a decided prominence to its more utilitarian aspects. Mr. Russell considers that there is still room for a text-book dealing with principles alone, and he has accordingly restricted his work to a discussion of the "more common and important problems." This programme does not, of course, afford much scope for originality of matter nor for novelty of treatment; moreover, it does not appear that either of these was the author's intention. The object aimed at, as a matter of fact, has been to produce a book "suited for use in a number of courses" (at the Massachusetts Institute of Technology) "where the amount of prescribed time and the ground to be covered varies in each course."

The volume is divided into ten chapters, dealing with hydrostatics; the laws of fluid motion; discharge from orifices; flow over weirs, through pipes and in open channels; and the dynamic action of jets and streams. Each chapter terminates with a number of problems, the solutions of which, however, are not given; and there are useful reference lists to other literature on the subject-matter. Most of these are American and English works, and one notes casually the omission of any mention of the studies of Boussinesq. Neither is there any account of streamline flow, and the experimental researches in this connection of Reynolds and Hele-Shaw. But these omissions may be due to the restrictions imposed upon the author by the object he had in view.

For the rest, the book is written in carefully considered sequence, the type is clear, and the diagrams are excellent. There is a very useful warning in the introduction to the inexperienced student who is apt to attach exaggerated importance to the precision of numerical results obtained from data which, in themselves, are liable to errors of observation of no slight moment. The warning can hardly be over-emphasised, for the writer of this article has frequently noticed the tendency of students to pursue the solution of problems to the third and fourth decimal place when the integers alone cannot be depended upon to the extent of 10, 20, or even 50 per cent. Such fallacious exactitude is perhaps more characteristic of the study of hydraulics than of any other practical science. B. C.

WORKS ON PHYSICS.

(1) *L'Électricité considérée comme Forme de l'Énergie.* Electrostatique. Première Partie. By Lieut.-Colonel E. Aries. Pp. 176. (Paris: A. Hermann et Fils, 1909.) Price 5 francs.

(2) *Lehrbuch der Physik.* By E. Grimsehl. Pp. xii+1052. (Leipzig: B. G. Teubner, 1909.) Price 15 marks.

(3) *Elements of Physics for Use in High Schools.* By H. Crew, revised by F. T. Jones. Pp. xiv+435. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 6*s*.

(4) *Light.* By Prof. R. C. Maclaurin. Pp. ix+251. (New York: The Columbia University Press, 1909.) Price 1.50 dollars, net.

(1) As suggested by the title, the author in this pamphlet proposes to alter the present method of measuring electricity. Usually the terms "charge of electricity" and "quantity of electricity" are regarded as synonymous. Colonel Aries wishes to draw a distinction between them. The former he regards in the usual way, but defines the latter as proportional to the electrostatic energy, *i.e.* half the product of the charge and the potential. The consequence of this definition is to arrive at the result that the *quantity* of electricity associated with an insulated conductor is not constant, but varies with change of potential, although the charge is unaltered. This the author explains by assuming that the electricity (meaning the quantity—in reality the energy) streams to or fro, as the case may be, between the conductor and the surrounding dielectric.

To this change of nomenclature the objection may be raised that it leads to no useful result. But Colonel Aries suggests that in this passage of so-called electricity is to be found the explanation of the residual charge of condensers, and that it is identical with Maxwell's "displacement currents." Both suggestions are absurd. However, the treatment of the subject does not follow this point of view. Most of the ordinary theorems in electrostatics are proved by the ordinary methods, and it is a little difficult to see why the author makes the above suggestions at all. The volume is not absolutely confined to electrostatics, digressions being made into current electricity and magnetism.

(2) This book covers in some detail the whole ground usually taken in a systematic study of physics. It cannot be described as elementary, as generally understood. The standard is about that required for the pass degrees in the British universities. Were it in English it could be thoroughly recommended to students taking such courses. Recent experimental work, particularly that concerning radio-activity and electromagnetic radiations, finds a place in the section on electricity, and a number of useful tables of physical constants are given in the appendix. The notation of the calculus is used only occasionally, and in most cases, *e.g.* the estimation of certain moments of inertia, simple integrations are performed by laborious methods which avoid that notation. This, we think, is undesirable in a book of this type. If a knowledge of the calculus on the part of the student is assumed —as undoubtedly it should be in this work—it should be used consistently throughout the book.

It is gratifying to find several chapters in the beginning in which the fundamental principles of mechanics are thoroughly dealt with. The greatest difficulty encountered in the teaching of physics is insufficient training of the students in this respect. We take exception, however, to the somewhat illogical order of this section. Weight and specific gravity are defined before the questions of force and mass have been considered, and the definition of the unit of mass as "that which weighs one gram in the latitude 45°" is entirely misleading. The book is well printed, and possesses a profusion of diagrams illustrating the experiments described in the text.

(3) It is not often that we meet with a book which so admirably fulfils the purpose for which it is written as this one. It is intended for those who are just commencing the study of physics, and it is written in a way that must appeal to the student. The reason, probably, is that reference is so frequently made to those common occurrences and mechanical appliances in which the principles of physics are involved. Also, although the treatment is quite elementary, phenomena such as the diffraction and polarisation of light are not avoided, as is usually the case in text-books of this class. A further novel feature is the practice of frequently giving references to books by other authors, in cases where the student wishes for a more exhaustive treatment of a particular section of the subject. Numerous worked examples are given, and some four hundred questions are set at the end of the book.

There are only two faults we have to find. The first is connected with the question of gravitation. It is at least suggested, although not positively stated, that the value of "*g*" should be greater at the bottom of a mine than at the earth's surface. The second fault is by no means peculiar to this book. It is the erroneous view that a particle describing a circular path is in equilibrium, and subject to *two* forces, one centrifugal and the other equal and centripetal. One may ask, "How is a student to reconcile this with Newton's first law of motion?"

(4) This volume consists of ten lectures on light,

given last year by Prof. Maclaurin in the American Museum of Natural History. The subject undertaken was a difficult one, namely, to treat from a non-mathematical point of view, and in such a way as to be understood by non-physicists, the more advanced portions of the optical theory. Prof. Maclaurin has, however, successfully done this. The lectures are extremely clear and full of information. Among the subjects dealt with are colour vision and colour photography, dispersion and absorption, polarisation, interference and diffraction, and the connections between light and electricity, such as the Zeeman effect. The lectures make very good reading, and would be appreciated even by those for whom the exclusion of mathematics is unnecessary.

FUNCTIONAL PSYCHOLOGY.

(1) *Genetic Psychology. An Introduction to an Objective and Genetic View of Intelligence.* By E. A. Kirkpatrick. Pp. xv+373. (New York: The Macmillan Company, 1909.) Price 5*s.* net.

(2) *The Psychology of Thinking.* By Dr. J. E. Miller. Pp. xxv+303. (New York: The Macmillan Company, 1909.) Price 5*s.* net.

(1) THERE seems to be an ever-increasing tendency among psychologists at the present day to assimilate not only their methods of procedure, but also the schemes of description and explanation underlying their science to those employed by biology. In place of, or, more accurately, in supplementation of, the older "introspective" psychology—including "introspection under test conditions"—we now find a "functional" psychology which treats of the individual mind from the point of view, primarily, of its usefulness in adapting the individual to his environment. Both the books under consideration are written from this point of view. They are, both of them, excellent examples of the use of the biological method. Mr. Kirkpatrick tells us in his preface that all psychology must be founded on genetic principles, and studied in close relation to the facts and theories of the other sciences of life phenomena. He himself therefore commences his book with a clearly written and somewhat full account of the forms of behaviour of the lower animals, together with their structural bases, selecting types at different stages of evolution for detailed description. Not until the middle of the book does he reach the subject of consciousness "as such," and even here he deals first with its objective aspect, viz. its external effects and criteria, as exemplified by human adult consciousness. The account is excellent, and conducive to clear thinking on a difficult subject. Following this, there are chapters on "specific conscious states," "types of adaptive activity or intelligence," "types of learning activity," and "racial and individual development."

The book should prove of very considerable value to students, since it sums up a great deal of recent monograph work in most clear and interesting form.

(2) Dr. Miller's book is inspired throughout by what he aptly calls a clinical interest in the thinking process as it occurs in the child's mind, in concrete form, at the various stages of its education. The earlier chapters are devoted to a general explanation and justification of the biological point of view, and form an excellent propædeutic to the predominantly pedagogical account of thinking which follows. By those educationists—and they must surely be many—who have become dissatisfied with the quasi-logical, almost scholastic, account of the thinking process given by the older school of psychologists, the author's treatment of his subject will be found both stimulating and refreshing. Thinking is kept throughout in its correct and natural close relationship with other forms of mental activity and general organic behaviour. Not abstract schemes, but actual concrete bits of thinking, are to be found skilfully analysed and classified on every page. The continuity between the empirical thinking of animals and children and the reasoning of the trained adult mind is well brought out, together with their specific differences, and throughout the entire account the author never loses sight of the fundamental characteristic of the life process as expressed in terms of the satisfaction of needs, which is the central and controlling idea of his psychological system. The book breaks new ground in its treatment of a hitherto neglected department of psychology, and will undoubtedly be welcomed by psychologists and educationists alike. W. B.

OUR BOOK SHELF.

Das Kaninchen. Zugleich eine Einführung in die Organisation der Säugetiere. Monographien einheimischer Tiere. Vol. ii. Pp. vi+307. (Leipzig: Dr. Werner Klinkhardt, 1909.) Price 6 marks.

FOLLOWING upon an industriously compiled volume devoted to the frog, this series, edited by Prof. Ziegler, is now represented by a work on the rabbit, which we may confess at once is a disappointing one. It is little more than a new edition of Krause's well-known work, with a few additional illustrations. Indeed, though more elaborate in detail, the treatment is hardly so good as that of any of the elementary treatises in which this familiar animal has been described. There are no practical directions for actual dissection, and the figures are singularly devoid of explanatory lettering, an omission which becomes ludicrous in the case of complicated musculature. The editor has not exercised sufficient control in that important respect, nor in the treatment of the various sections, bones and muscles being allowed far too large a share in a purely descriptive work.

The book begins well, and, in fact, the introduction is its saving grace. The author treats in this opening section of the relation of the rabbit to its congeners, the differences between rabbits and hares, the various races, their habits, and history. Then follows a section upon diseases and parasites, but without any figures of the latter and without any mention of the two commonest cestodes, *Cysticercus pisiformis* and *Coenurus serialis.* Then follows an account of how to kill the creature, and, having done so, the author treats it for the whole of the rest of the work as dead. The book is a study in necrology. We are not told how the rabbit breathes or digests, or how it does anything. Are there sweat-glands? The index throws no light on the subject. What is the structure of the skin? A page near the end of the book, without a single figure to explain the heavy vocabulary, is all we are vouchsafed. The treatment of histological and embryological data is almost useless. A drawing of a sagittal section of the head raised hopes of a description of the course taken by the air in the act of breathing, but on examination the drawing itself is seen to be incomplete and to illustrate the tear-duct.

What is wanted in a modern monograph is no exclusively anatomical study of individual bones and muscles, expressed in a deterrent vocabulary, but a treatment seasoned with morphological and physiological "salt." This series is intended to help beginners, but a more strange method of doing so it would be hard to imagine. We trust that future volumes of this collection of monographs will be planned with a little more insight into the needs of biological students, and written with some feeling of the beauty as well as of the complexity of the subject.

The Irish Fairy Book. By Alfred Perceval Graves. Illustrated by George Denham. Pp. xv+355. (London: T. Fisher Unwin, n.d.) Price 6*s*.

There is a greater demand for fairy books than there is for works on folklore, and the readers differ greatly in taste and requirements. Some fairy books are worse than useless to the folklorist, books in which the authors treat their sources in a thoroughly irresponsible fashion. On the other hand, those who could handle such materials discreetly, learnedly, and reverently cannot be induced to write fairy books. But such books must be written, and Mr. Graves has produced one which is in every respect commendable.

Apart from a helpful preface and one short poem by the author or compiler, the book is a symposium by Irish writers of folk-tales, and a bare list of the writers' names shows the comprehensiveness of the work:—O'Grady, Kennedy, Allingham, Croker, Gregory, Zeats, O'Looney, Ewing, Ferguson, Joyce, McClintock, Carleton, Campbell, O'Kearney, Lover, Curtin, Wilde, Le Fann, Mangan, Hyde, Sigerson, Hull, Larminie, Boyd, Hopper, with Tennyson's "Voyage of Maeldune" as a fitting conclusion. The book is just what it was intended to be—delightful reading.

Many of the tales are in proper form for scientific examination, being evidently faithful records of oral traditions, which, with Mr. Denham's apt illustrations, are as "readable" as any in the collection. All the stories are replete with useful facts of folklore. The frequent identification of Druidism with magic is very impressive. As in Welsh folklore, the fairies are in high glee at the seasonal festivals. Puck, for instance, is definitely associated with November. Lugnassed, Lug's marriage—the old name for the August festival—survives in dialect as "Lu*nacy* day in harvest." That the framework of the tale is the calendar is in most cases fairly obvious, and one regrets that the compiler offers the reader no clue to such an interpretation in a preface where other theories are mentioned.

John Griffith.

Space and Spirit. A Commentary upon the Work of Sir Oliver Lodge entitled "Life and Matter." By R. A. Kennedy. Pp. 64. (London: C. Knight and Co., Ltd., 1909.) Price 1*s*. 6*d*. net.

This is a commentary on Sir Oliver Lodge's work, "Life and Matter," which was written primarily as a counterblast to Haeckel's "Riddle of the Universe." Its author agrees with Sir Oliver in regarding Spirit as the ultimate Reality, of which the Universe is a manifestation; but he differs on a few points of detail. Moreover, though Spirit is the "unknown reality," there is another irresolvable Absolute, viz. Space. There is a Spacial universe and a Spiritual universe. The former may only be a branch or out-leaking of the latter, but the two cannot be identified. Mr. Kennedy is, therefore, not a monist, even of the spiritual variety; he recognises two entities, and not merely two aspects of the same substance. (But is it not self-contradictory to speak of *two universes?*)

The most vital detail on which the author disagrees with Sir Oliver Lodge is that of the nature of Life. Sir Oliver, combating Haeckel's explanation of life (which gets out of the difficulty by attributing a kind of life to the atoms, in fine *petitio principii* style), Sir Oliver, we say, supposes life to flow into the carbohydrate molecule from a supernal life-reservoir, as soon as the molecule becomes sufficiently complex to accommodate it or to "let through" the properties which life can manifest. The materialist's view is that the complex aggregate has *generated* the life; he does not stop to ask what generated the complex aggregate; and Mr. Kennedy thinks that Sir Oliver is rather similarly inclined to leave the formation of the organism in its early stages to chance. "The right view surely is that life is in operation from first to last, and in fact generates the organism."

In discussions of these questions which lie on the borderland between science and philosophy, it is often apparent that divergences are verbal only. It is probably thus to some extent in the present instance. Certainly, life does not manifest itself except through complex molecules, but Sir Oliver does not leave the formation of those molecules to "chance." Rather, he would say that all matter allows intelligence and will to shine through—somewhat as taught by two men as different as Shelley and Prof. William James—from the spiritual sun which is Reality. But he is still right and consistent in denying Haeckel's assumption that atomic forces explain life, however aggregated.

The booklet is well written, and the argument is extremely acute and suggestive throughout.

Introduction to the Preparation of Organic Compounds. By Prof. Emil Fischer. Translated by Dr. R. V. Stanford. Pp. xix+175. (London: Williams and Norgate, 1909.) Price 4*s*. net.

Emil Fischer's "Anleitung zur Darstellung organischer Präparate" first appeared in 1883 in the form of autograph copies for the use of his students in the Erlangen Laboratory, and represents the first published introduction to the practical study of organic chemistry. The increasing demand led to its appearance in book form in 1887, and from it an English translation was made by A. Kling, which reached a second edition in 1895.

The book has apparently been more popular in Germany than here, for the present translation is made from the eighth German edition. This is no doubt due to the publication of more comprehensive and elaborate treatises on the same subject by English writers. But whatever the cause, the modest proportions of the volume before us do not diminish its practical value, as both teachers and students who have used it will readily admit. In this last English edition a second part is added, which is drawn from the author's researches on physiological chemistry, and is intended more especially for medical and biological students. The book is neatly bound, and printed in good type.

J. B. C.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Meaning of "Ionisation."

I AM sorry that Prof. Walker (p. 458) has avoided my question. At present I am not concerned either with his position or with mine, with van der Waals or with Newton—I wish simply to know *what exactly he would have us understand by the word ionisation.* I hold that it is our duty, as scientific workers, if possible, to be exact in word as well as deed. It is a matter of reproach to us that we should be lectured, year after year, from the chair of the Royal Society, for our carelessness as writers. Now that the attempt is being made to standardise all sorts of things—from amperes and ohms to the members of iron bridges, even by means of international congresses—we might well devote some attention to our words and attempt to standardise our scientific nomenclature. *Ionisation* is a word used with increasing frequency in these days—unfortunately also with increasing ambiguity. I would appeal to Prof. Walker, as a leader among British physical-chemists, at least to tell us what he wished us to understand when using the word recently—as his meaning is in no way made clear in his article.

HENRY E. ARMSTRONG.

The Flow of Sand.

ON Friday, February 11, I had the pleasure of hearing Mr. C. E. S. Phillips deliver the discourse at the Royal Institution, illustrated by many experiments, a number of which showed that when sand escapes from an orifice at the bottom of a long vertical tube it does not do so perfectly uniformly, but in a series of pulses which are sufficiently rapid to produce audible sounds. Mr. Phillips did not offer any suggestion as to the reason why the flow is regularly intermittent, but two of his other experiments, and the laws of friction, suggest a possible cause.

One experiment showed sand forming a cone on being poured from a funnel. The sloping sides of the cone gave the angle of repose, and it was noticed that the sand at first did not flow steadily down the slopes, but intermittently. This, I think, may be due to a combination of the momentum of the sliding sand and the difference between the statical and dynamical friction between the particles of the sand. A little heap of sand collects, then the statical friction is overcome, and the momentum carries the sand slightly too far, thus making the angle of repose too small; consequently the on-coming sand is able to remain stationary on the slope until in turn its angle of repose becomes too great, the statical friction is overcome, and the cycle is repeated. The other experiment showed how sand is self-supporting in a tube except for the cone of sand at the base. Allow this cone of sand to pass through the orifice, and the rest will fall intermittently in the manner indicated.

If this theory is correct, one would expect sand with a comparatively large coefficient of statical friction to give fewer pulses per second than a sand having a smaller angle of repose.

A. S. E. ACKERMANN.

25 Victoria Street, Westminster, London, S.W.,
February 14.

I AGREE with the explanation offered by Mr. Ackermann in the first part of his letter, for it is evident that sand must slip down itself by a series of rushes.

The process, however, by which a mass of sand falling in a glass tube produces musical sounds is somewhat more complicated. The column must be regarded as consisting of two parts, the upper portion acting simply as an intermittently moving piston. It is the central region of the lower part which becomes less dense, owing to escape of sand through the orifice; the upper portion, being no longer supported, slips downward as a whole.

The rapidity of its intermittent motion depends upon the friction between the glass and sand. Hence the pitch of the note is raised if the grains are better packed. The action appears to resemble that of pushing a moist finger-tip along a polished table. The finger jumps rapidly and regularly.

As soon as the column so far lowers that the previously compact upper portion begins to fall away at its centre, all sound ceases. I showed at the Royal Institution that by coating the inner surface of the glass tube with oil, before filling it with sand, the column moved downward by slow, regular jerks, increasing in rapidity as the mass of the remaining sand in the tube grew less. Here all friction between the glass and the sand grains was eliminated, on account of the outer layer of particles adhering to the oil and remaining as a coating upon the tube.

The jerks became more rapid as the inertia diminished with the decreasing mass, which also explains why the pitch of the note given out by a tube rises somewhat as the sand column diminishes.

CHARLES E. S. PHILLIPS.

Castle House, Shooters Hill, Kent, February 15.

The Heredity of Sex.

CURRENT Mendelian theories of the heredity of sex are based on the assumption that gametes are pure with respect to sex characters; that is, that a gamete may carry the factor for maleness or the factor for femaleness, but not both. This view may be expressed thus:—a gamete carries M, the factor (or factors) for maleness, or F, the factor (or factors) for femaleness, but not both M and F.

The hypothesis proposed in this note suggests that the phenomena of sex are due, not to a single pair of allelomorphic characters, but to two independent pairs of characters, namely, maleness (M), with its allelomorph, absence of maleness (*m*), which constitute one pair, and femaleness (F), with its allelomorph (*f*), which constitute the other pair. On this hypothesis, since M*m*, F*f* are independent of one another, representatives of both pairs of characters occur in every gamete.

All gametes are therefore of one or other of the following sex constitutions, MF, M*f*, *m*F, *mf*. Hence all zygotes produced by the pairing of such gametes are of one or other of the following nine gametic constitutions:—

$$\text{Dihybrid scheme}\left\{\begin{array}{l} \left.\begin{array}{l}1\ \mathrm{MMFF}\\ 2\ \mathrm{MMF}f\\ 2\ \mathrm{M}m\mathrm{FF}\\ 4\ \mathrm{M}m\mathrm{F}f\end{array}\right\}9\ \mathrm{MF}\\ \left.\begin{array}{l}1\ \mathrm{MM}ff\\ 2\ \mathrm{M}mff\end{array}\right\}3\ \mathrm{M}f\\ \left.\begin{array}{l}1\ mm\mathrm{FF}\\ 2\ mm\mathrm{F}f\end{array}\right\}3\ m\mathrm{F}\\ \begin{array}{l}1\ mmff\end{array}\quad\ \ 1\ mf\end{array}\right.$$

In zygotes MMFF and M*m*F*f* it may be predicted that circumstances, nutrition, &c., determine which type (male or female) of sexual organs is produced.

Thus double begonias, which bear female flowers, may be induced by starvation to bear male flowers. Fern prothalli, which bear normally male and female organs, produce, when subjected to special treatment, male organs only, and so on.

In general, the numbers of "males" and "females" among MMFF and M*m*F*f*, zygotes, will be about equal, though wide departures from equality may occur in any species owing to the prevalence of conditions which favour the production of male or female organs.

The following types of zygotes will, it may be supposed, produce male sexual organs, MMF*f*, MM*ff*, M*mff*, and the following, female organs, M*m*FF, *mm*FF, *mm*F*f*; hence the number of males will equal the number of females produced by such zygotes.

The *mmff*, pure recessive type of zygote, if viable, is sterile. The origin of sexuality connotes an origin of sterility. To give examples of the application of the hypothesis to biological facts:—

A zygote of the MF type produces gametes of which all or some carry MF. Species which have MF gametes will be capable of exhibiting parthenogenesis (natural or induced). Certain of the lower algæ produce "gametes" which may fuse in pairs to form zygotes, or may develop directly into new individuals. Those which behave in the former fashion may be such as carry M*f* or *m*F, and those which develop directly may be the MF gametes.

Among moulds, certain species of Mucor exist as several races the individuals of each of which reproduce themselves asexually, but do not conjugate with one another. When, however, individuals of different races meet, they conjugate and produce zygospores. It may be supposed that one race is of such a type as $MMff$, another of the $mmFF$ type. In this case verification of the hypothesis is possible.

The absence of sexual reproduction in various groups of fungi is to be explained on the present hypothesis as due to the extinction (or effective separation) of all zygotes except those of one type, *e.g.* the Mf or the mF types.

In homosporous ferns, the spores, produced after the reduction division, give rise each to a prothallus which bears male and female organs. If it be allowed that the reduction division is of fundamental significance with respect to the segregation of characters, it would appear to follow that current Mendelian theories of sex-heredity fail to account for the fact that a spore produced as a consequence of the reduction-division may yet carry "male" and "female" factors.

The phenomena may be interpreted simply in terms of the new hypothesis. The fern plant is MMFF; the spore, and hence the prothallus, carries MF. Therefore male and female organs may be produced by the prothallus. The gametes formed and matured in the female organs are "female," those formed and matured in the male organs are "male."

In the heterosporous ferns the spores are of two kinds, macrospores, giving rise to "female" prothalli, and microspores, which give rise to "male" prothalli. In terms of our hypothesis the sporophyte (zygote) is $MmFf$, the megaspore mF, and the microspore Mf.

Further, the high rate of mortality which accompanies spore-formation receives on this hypothesis an intelligible explanation. It is due to the inevitable reappearance of combinations of sex-characters which the heterosporous fern has ceased to tolerate.

In the light of the present hypothesis, homosporous ferns are homosporous because they are homozygous, and heterosporous ferns are heterosporous because they are heterozygous for the sex characters M and F.

The significant question arises, How far is the present limitation of characters presented by any great group of organisms determined by the fact that in this group the task of reproduction has come to be committed to some particular type or types of gametes?

The hypothesis would appear to throw light on large numbers of known facts, on prepotency, partial sterility—such, for example, as occurs in heterostylism—the apparently excessive production of pollen and ovules, and so forth.

Not only is it not repugnant to a reasonable explanation of many facts, but also the hypothesis does not seem to be inherently improbable. In that it is based on the presence and absence theory, it receives the sanction of Mendelism. It tempts the imagination to trace the origin of sexuality from the "self-contained" organisms of the MF type. Evolution in such types took, in some individuals, the form of a dropping out of the M, in others, of a dropping out of the F, factor. Such incomplete forms as Mf and Fm discovered in fusion the means of restoring their constitutions; but out of this fusion possibilities for novel constitutions arose, for the $MmFf$ type of zygote was now in being. In reproducing by segregation the original MF type of gamete, the zygote was constrained to produce likewise the other possible combinations of Mm and Ff. Fusions between the several types resulted in different forms of zygote; evolution had its chance.

Among other types, the pure recessive, $mmff$, arose, and, with its advent, sterility, and, it may be, death, came on the scene as the sinister shadow of "sexual" reproduction.

It only remains to add to this note that—in case the hypothesis it proposes prove of value—though the responsibility for the hypothesis rests with the writer, the stimulus to which it owes its inception originated, in the first place, from a study of Bateson's work on heredity, and in the second place from discussions on the problems of heredity between the writer and his colleagues, Miss Rayner, Mr. Jones, and Miss Pellew, of the botanical laboratory, to whom certain of the foregoing illustrations are due.

University College, Reading. FREDERICK KEEBLE.

Geology and the Earth's Axis of Rotation.

FROM time to time the pages of NATURE contain references to the theory which would explain the occurrence of Ice ages by a hypothetical shifting of the earth's axis of rotation. On the face of it, the theory in question appears to be capable of explaining a good deal more than this.

In the first place, if the axis of rotation were to be shifted, it seems clear that the relations between the earth's hydrosphere (or hydrospheroid) and the lithosphere must undergo change. In the regions towards which the pole is approaching land will tend to emerge from the sea, and *vice versa*. If the effects of this supposition be traced out in detail, they will be found to furnish an explanation of such phenomena as raised beaches, submerged river valleys, varying continental connections, &c., without postulating violent alterations in the lithosphere itself. Speaking merely qualitatively, the hypothesis seems to fit the facts pretty closely, *e.g.* (*a*) the height of raised beaches tends to increase as one approaches the polar regions, as it ought; (*b*) a marine transgression is associated with a warm climate.

In the second place, a shifting of the polar axis will not be without effect on the lithosphere itself, although such effect would not, presumably, under present conditions, at all resemble the effect on the hydrosphere already alluded to. Even in a rough qualitative way this effect is not easily traced out, but it seems tolerably clear that it will account for those processes of folding, &c., whereby mountain chains are built up, and also for extensive local subsidences such as are believed to have occurred in geological time. These, and doubtless other phenomena, the hypothesis explains without having recourse to the supposition that the earth has been undergoing contraction through loss of heat.

I am not aware of the existence of any publications dealing with the matters referred to, but as the subject appears to be not without interest, perhaps some of your other readers will be able to refer me to papers, &c., treating of the subject with which they may be acquainted. I should be particularly glad to be referred to researches in which the subject is treated quantitatively.

Secondary Cells in Tropical Climates.

ALL who have used batteries of small secondary cells in the tropics will have experienced the difficulty of keeping their cells in efficient working order, and especially in preserving the junction of separate cells from rapid corrosion. The difficulty, appreciable in Europe, becomes very serious in a climate where the laboratory temperature lies between 30° and 40° C., and for this reason—it is probable that practically all accumulators sent to tropical countries by European manufacturers are filled by their recipients with dilute sulphuric acid of a density (1,190) which corresponds to a 20 per cent. mixture in north Europe at 15° to 20° C., but at a temperature of 30° to 35° C. indicates a mixture which is far too rich in acid for the health of the cells. Some simple experiments recently carried out in this laboratory exhibit quite clearly how large a deviation from the standard 20 per cent. mixture is caused by filling cells at 30° with dilute acid of density 1,190. It is found that a density of 1,190 at 30° corresponds to a composition of 23 per cent., whereas the value of the composition accepted as giving the best results with cells of this type is 20 per cent. The difference is as much as half the total change in composition due to chemical action during the process of charging the cell.

The conclusion reached from an examination of the density-temperature curves for dilute sulphuric acid points to the advisability of filling all secondary cells in localities where the average temperature is 30° or more with acid solution of density about 1,170. Densities as low even as 1,150 have been found satisfactory for small secondary cells in the hot weather in Calcutta.

In the case of large plants in power stations, the matter may be still more important, as a cell containing too strong

an acid solution is likely, not only to live a shorter life, but to suffer sooner and more severely from sulphating and other diseases.

The Invention of the Slide Rule.

DR. ALEXANDER RUSSELL's remarks on the invention of the slide rule (NATURE, January 13, p. 307) are of great interest, particularly his reference to Seth Partridge. There can be no doubt that Partridge deserves much credit for improving the rectilinear slide rule, but I see no escape from the conclusion that the real inventor of the rectilinear slide rule is the one who first made two Gunter's scales to slide together, for purposes of computation. The man who did this is Oughtred. In Mr. Sidney Lee's "Dic. of Nat. Biog.," article "Partridge, Seth," and in other publications, the incorrect statement is made that Partridge's book, "Description, &c., of the Double Scale of Proportion," first appeared in print in 1671 or 1672. I have a copy of the book bearing the date 1662. The manuscript was finished; "Saturday night, August first 1657." In 1662 Partridge's rules were manufactured, not by Walter Hayes, but by "Anthony Thompson, living in Hosier-Lane near West Smithfield, in London."

There is another point of interest. The earliest account of the rectilinear slide rule, printed in Germany, is in Leupold's "Theatrum Arithmetico-Geometricum," Leipzig, 1727, p. 71. Leupold says that he had a manuscript of ten sheets, describing it, but that he did not know the name of the author or the inventor of the instrument. Leupold's description consists of translation, word for word, of extracts from Partridge's book. Thus a historic connection is established between the rectilinear slide rule in England and in Germany.

Aged Tadpoles.

THE experience of your correspondent Mr. John Don (February 17, p. 458) is no new one. More than twenty years ago we had in a small aquarium in the Charterhouse Museum a tadpole two years of age. To the best of my recollection this veteran never acquired any legs, either hind or front, but the head and body were extraordinarily large. At the present moment I have in my laboratory seven living tadpoles reared from spawn deposited last spring. Of these, three only have developed hind legs. These appendages appeared rather suddenly in December, a few days after I had supplied, for the first time, some fragments of hard-boiled egg.

The secret of procuring these aged tadpoles is to keep the animals in a vessel with vertical sides, and to afford as little opportunity as possible for them to wriggle into shallow water. I maintain a depth of about 5 inches of water in the aquarium, and find that a subdued light favours the health of the tadpoles. Sexual maturity can hardly be expected until at least the normal period has elapsed, viz. in the third or even fourth year.

Title of the Natural History Museum.

IN NATURE of February 17 you say (p. 465):—"No one, so far as we know, has suggested a suitable and adequate title for the [museum] at South Kensington" (devoted to natural history). This is not a difficult question; I think "British Museum of Natural History" is both suitable and adequate.
BERNARD HOBSON.

Tapton Elms, Sheffield, February 18.

THE NEW CANALS OF MARS.

THE word "new" when applied to a celestial phenomenon may be used in either of two senses. It may mean new to earthly observation, *i.e.* one which has never been seen by human beings before, or, secondly, new in itself, that is, one which has had no previous existence. New canals on Mars in the first sense, though always interesting, and at times highly important, are no novelty at this observatory, inasmuch as some four hundred have been discovered here in the last fifteen years. When Schiaparelli left his great work, he had mapped about 120 canals; with those detected here since, the number has now risen to between five and six hundred. Each of the four hundred thus added to the list, however rich an acquisition at the time it first came to be noticed, was not necessarily otherwise remarkable.

To observe, however, a canal new in the second meaning of the word, one, that is, that had never existed anteriorly, and to prove the fact, is an astronomical detection of far-reaching significance for the bearing it has upon the whole Martian question.

On September 30, 1909, when the region of the Syrtis Major came round again into view, after its periodic hiding of six weeks due to the unequal rotation periods of the earth and Mars, two striking canals were at once evident to the east of the Syrtis in places where no canals had ever previously been seen. Not only was their appearance unprecedented, but the canals themselves were the most conspicuous ones on that part of the disc. They ran one from the bottom of the Syrtis (lat. 20° N., long 285°), the other from a point part way up its eastern side (lat. 17° N., long 284°), and, curving slightly to the left as they proceeded south, converged to an oasis, itself new, on the Cocytus (lat. 5° N., long 265°), about two-thirds of the distance to where that canal meets the Amenthes. The Amenthes itself was not visible, except possibly as a suspicion. With the two main canals were associated several smaller ones, and at least two oases which had never been seen before, and from the interconnection of all of them these clearly made part of the new piece of Martian triangulation.

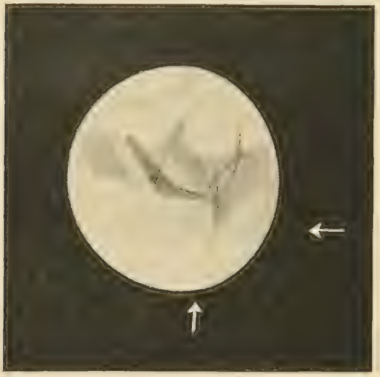
The phenomena were recorded in many independent drawings by Mr. E. C. Slipher and the director, and in the course of the next few days were photographed, appearing on the plates to the eye as the most conspicuous canals in the presentment of the planet. It is opportune that detailed photography of Mars in Mr. Lampland's skilful hands should have been so perfected as to make this possible; for the photographs taken by both Mr. E. C. Slipher and the director record these canals so that anyone may see them. There are thirty images, more or less, on each plate, and the canals appear on every image; on some more distinctly than on others, owing to the state of our air at the time, but recognisably on all; for each image had a pose of about two seconds and a half, and its definition varied according to the seeing at the time. Owing to the grain of the plate being much coarser than that of the eye, the two canals appear merged in one in the photographic images as a single line, its linear character, however, being quite distinct to one of good eyesight.

The photographs of this region taken in 1907 show no such feature.

No remembrance of ever having seen them before could be recalled by either observer, both being familiar with the planet, except that Mr. Slipher turned out to have drawn one of them the evening previous.

The record books were then examined, when it appeared that not a trace of them was to be found in the drawings of August, July, June, or May when this part of the planet was depicted. That they had not been observed in previous years was then conclusively ascertained by examination of the records of those years. The record of canals seen here is registered after each opposition in a fresh map of the planet's surface. This has been done since the beginning of the critical study of Mars at this observatory in 1894. Now, when these maps came to be scrutinised for the canals, each of them failed to show any such features. Nor had any observer previous to 1894 recorded them, as the observatory library of the subject bore witness. Schiaparelli had never seen them, nor had his predecessors or successors. This determined definitely that no human eye had ever looked upon them before. But, stirring as it is to know that one is the first to see a new geographical feature on another planet, akin to the thrill of finding unknown land in our own Antarctic regions, a much deeper scientific interest attaches to the question whether a phenomenon previously undiscovered was also previously non-existent. For in that case one has seen something come into being, with all that such origination implies.

It might seem to persons not versed in the subject that its absence on the charts was proof that a canal was itself new in the second sense because it was so in the first; but study of Mars has shown that this cannot be taken off-hand for granted. Several points must each be carefully considered. In the first place, one must be sure that the phenomenon could have been seen before, yet was not. It must be of a size which could not have escaped detection previously. Now, the great majority of canals discovered here were beyond the hope of detection elsewhere, owing to the character of the air, the improvement in instrumental means, and the long acquired knowledge of the observers. That they were not seen by Schiaparelli, therefore, by no means implies that they did not exist in his day—or even in the earlier days of observation here. We see to-day vastly more than we did in 1894, because of the experience acquired since. In the present case, however, this possibility of error was excluded by the size of the canals in question. They were not difficult detail of the order here mentioned, but, as I have said, the most conspicuous on the disc, canals which no observer of any standing whatever in good air could possibly pass by. They would strike any skilled observer of such matters the moment he looked at the planet. So far as this point went, then, they could not have existed before.



New Canals on Mars, November 4 (Prof. Percival Lowell).

The next point to be considered was whether they were results of a characteristic of the planet of vital import in its cartography—the annual seasonal change which affects all its features. For the world of Mars is as subject to recurrent seasonal change as our own, and more markedly so. This change stamps itself unmistakably upon all its features, obliterating some and bringing into prominence others according to the time of the Martian year. Examples of this occur in the study of Mars regularly at each opposition, the aspect of the disc varying according to a definite law dependent on the Martian season. To be sure, therefore, that a canal is itself new, the planet must have been previously carefully depicted at the same season of its year, and then when these earlier drawings are critically scanned the canal in question not found recorded on them. Now, the possibility of definite and conclusive intercomparison of the sort is not presented so frequently as one might think. Mars comes to opposition each time later and later by about two and a quarter of our own months. This means that we meet him in a different part of his orbit at each fresh approach, and so at a different season of his year. Now, until Schiaparelli's time, it was at or near opposition only that his face was studied. Schiaparelli extended the time greatly, but not until the subject was taken up at Flagstaff was the period of observation prolonged to six and eight months for each opposition epoch, thus enabling the same Martian season to be recurrently viewed by the seasonal overlapping of two or more observation periods.

But even so, the disc is not equally well presented in successive Martian years, because of the differing distances the two bodies are apart, and the difficulty of consequent comparison on the score of size. Still another difficulty in the way of parallelism is that of phase. Unless the two bodies be exactly opposite at the same season of the Martian year in the two cases, Mars will show a differing phase at each, and this means a different slant in the illumination. This is a very important distinction, because the disc shows very diversely when illuminated from above or from the side, so diversely that faintness of detail has often been attributed to intrinsic weakness of feature when illumination itself was the cause.

In consequence, the observer can never be quite sure that his data are comparable until he has himself seen the Martian disc under like conditions, or nearly such, which recurrent presentations demand a lapse of fifteen to seventeen years.

Furthermore, to be conclusive, the observations must all have been made by the same observer, working under like conditions, and grown, in consequence, familiar with every detail of the disc, since the personal equation, including by that term the site and the instrumental methods and equipment, is always a factor. A Martian cycle, that is, a round of about sixteen years, must have been gone through by the same observer before definite judgment can be pronounced. Such a cycle now stands complete at Flagstaff.

Examining the records here we find that Mars was observed four times previously at the same season of the Martian year as occurred during the epoch of the appearance of these two canals. The canals were seen at this opposition as follows:—

	1909	⊙	In Martian relative chronology Northern Hemisphere	Hel. long. of planet	Opposition
First appearance	Sept. 30	277°	Jan. 6	4° 50′	Sept. 23, 1909
Last observed	Dec. 12	320°	Feb. 17	47° 43′	

The previous occasions on which the canals should have been visible, if their appearance or non-appearance were a consequence of the Martian season, were:—

	☉	Martian date	Opposition
1894 Sept. 8	277°	Jan. 6	Oct. 20, 1894
to			
Nov. 18	320°	Feb. 17	
1896 July 25	277°	Jan. 6	Dec. 10, 1896
to			
Aug. 23	320°	Feb. 17	
1898 July 12	295°	Feb. 9	Jan. 18, 1899
to			
Aug. 23	320°	Feb. 17	
1907 Nov. 12	276·5°	Jan. 6	July 5, 1907
to			
Jan. 25	320°	Feb. 17	

During all these periods the planet was kept under observation at Flagstaff, and during none of them were any such canals recorded. We are, therefore, sure that seasonal change cannot explain them, and that two years ago, and also eleven, thirteen, and fifteen years ago, no such canals existed. In Martian chronology this means that not only did they not exist in their present state during the previous Martian year, but also not four, five, and six Martian years before that. It is also fairly sure that they were not in existence thirty and thirty-two years ago, inasmuch as Schiaparelli never saw them.

Lastly, a further point disclosed by the Flagstaff observations must be reckoned with, a point of very singular significance. It was long ago discovered there that (see Bulletin No. 8 of the Lowell Observatory), while the great majority of the canals are quickened into conspicuousness alternately every six Martian months, first from the south and then from the north polar cap, certain ones respond only to one or the other cap, remaining inert to the action of its antipodal fellow. To be sure, therefore, that the new canals were really new to Mars, the old drawings had to be examined on this score too. Here again the records were decisive. No such canals had ever appeared before from the quickening of either cap at the time when, had they existed then, they should have showed.

The canals in question, therefore, proved to be, not simply new canals to us, but new canals to Mars. In the canal system they are *novae* in fact or function, and as such are the most important contribution to our knowledge of the planet of recent years. For let us see what they imply. In form they are like all the other canals, narrow, regular lines of even width throughout, running with geometric precision from definite points to another point where an oasis is located. This oasis resembles all the other oases, a small, round, dark spot. They partake, therefore, of all the peculiar features of the canal system, features which I have elsewhere shown make it impossible of natural creation, that is, of being the result of any purely physical forces of which we have cognisance. On the other hand, the system exactly resembles what life there would evolve under the conditions we know to exist. The present phenomena, then, show that the canals are still in process of creation, that we have actually seen some formed under our very eyes.

Thus, on every point which had to be considered, the records furnished conclusive evidence that the canals in question could not have existed in past Martian years in the condition in which we observe them to-day. Their previous non-visibility could not have been due to any of the causes which might possibly affect it, to wit:—(1) Want of size; (2) any personal equation of the observer; (3) improved instrumental or atmospheric means; (4) distance (all these are negatived by their striking conspicuousness); (5) phase; (6) regular seasonal change; and last (7) unihemispheric seasonal change.

It will be perceived that the proof that these canals are *novae* has been possible, and only possible, through the long systematic work done on the planet here for the last fifteen years. Without such a complete system of records the certainty that the canals in question were new canals *to Mars* could not have been reached.

PERCIVAL LOWELL.

Lowell Observatory, Flagstaff, A.T.

PROPERTIES OF POLONIUM.

THE statements regarding polonium which appeared in the report from Paris reprinted from the *Times* in NATURE of February 17, must have surprised many readers to whom polonium has been a familiar substance for the last ten years. It may be of interest to review briefly our present knowledge of polonium and the bearing of the recent work of Mme. Curie and Debierne upon it.

Polonium was the first of the active substances separated from pitchblende residues by Mme. Curie. Various methods of concentration were devised by her, with the result that preparations of polonium mixed with bismuth were early obtained many thousand times more active than uranium. Marckwald later separated from 15 tons of pitchblende about 3 milligrams of intensely active material which he called radio-tellurium, since it was separated initially with tellurium as an impurity. By dipping a copper plate into a solution of this substance, he obtained a deposit of weight not more than 1/100 milligram, which was far more active than an equal weight of radium. It was soon recognised that this preparation was identical with polonium, for it gave off the typical α radiation, and had the characteristic rate of decay of that substance. Unfortunately, Marckwald was not aware at the time of separation of the great importance of testing whether lead appeared as a product of transformation of polonium. Before such an experiment could be made, the polonium had to a large extent been transformed.

Polonium is one of the numerous transition elements produced during the transformation of the uranium-radium series. It is half-transformed in about 140 days, emitting α particles during the process. Rutherford showed in 1904 that polonium was in reality a transformation product of radium itself. Radium at first changes into the emanation, and then successively into radium A, B, C, D, E, F, radium F being identical in all respects with the polonium directly separated from a radio-active mineral. When the radium emanation is allowed to decay in a sealed glass tube, the walls of the tube are coated with an invisible deposit of pure radium D, radium E, and radium F, but the amount of the latter to be obtained in this way is far too small to be weighable.

The amount of polonium present in any radioactive mineral can easily be calculated. Since the radium and polonium (radium F) in a mineral are in radio-active equilibrium, the same number of α particles are expelled from each per second. Since polonium is half-transformed in 140 days and radium in 2000 years, the former breaks up 5000 times faster than the latter. The maximum amount of polonium to be obtained from a mineral is in consequence only 1/5000 of the amount of radium. In 1000 kilos. of pitchblende containing 50 per cent. of uranium, there are present 170 milligrams of radium. The weight of polonium is about 1/5000 of this, or about 1/30 milligram. It is thus obvious that to obtain 1/10 of a milligram of pure polonium, several tons of high-grade pitchblende must be worked up. The most natural source of polonium is radium D (radio-lead), which grows polonium and has a period of half-transformation of [illegible] y years. Since polonium breaks up about [illegible] faster than radium, its activity, weight for [illegible], should be about 5000 times greater than that [illegible] um. There is nothing surprising in this, for the [illegible] am emanation has an activity about 200,000 times of radium, while radium A (period three minutes) have an activity 400 million times that of radium itself. Since the radiation from polonium is entirely in the form of α rays, it is to be expected that the radiation from it would show chemical and physical effects identical with those observed for pure emanation, the only difference being that the products of the latter emit β and γ rays as well.

Apart from the interest of obtaining a weighable quantity of polonium in a pure state, the real importance of the present investigations of Mme. Curie lies in the probable solution of the question of the nature of the substance into which the polonium is transformed. This problem has been much discussed in recent years. Since polonium emits α particles, one of its products of decomposition, as for all the other α-ray products, should be helium. The production of helium from a preparation of polonium has been observed by Rutherford and Boltwood (Manchester Lit. and Phil. Society, November 30, 1909), and also by Mme. Curie and Debierne in their present experiments. Boltwood several years ago suggested that the end product of the radium series was lead, and has collected strong evidence in support of this view by comparing the amount of helium and lead in old radioactive minerals. Since polonium is the last of the active products observed in the radium series, it is to be expected that polonium should be transformed into helium and lead, one atom of polonium producing one atom of helium and one atom of lead. This point of view receives additional weight from consideration of the atomic weight to be expected for the end product of radium. Since in the uranium-radium series, seven α particles, each of which is an atom of helium of atomic weight four, are successively expelled before radium F is reached, the atomic weight of polonium should be 7×4=28 units less than uranium (atomic weight 238·5). This gives an atomic weight of polonium of 210·5, and after the loss of an α particle, a final product of atomic weight 206·5—a value very close to the atomic weight of lead.

It is a matter of very great interest and importance to settle definitely whether polonium changes into lead. The evidence as a whole has long been in favour of that supposition. The outlook is very promising that the experiments of Mme. Curie and Debierne will settle this question conclusively. No doubt, an interval must elapse to allow the polonium to decay before the final examination of the residual substance can be made.

E. RUTHERFORD.

THE DISCOVERY OF A SKELETON OF PALÆOLITHIC MAN.

DR. CAPITAN and M. Peyrony are to be congratulated on another important discovery of the remains of Palæolithic man on September 17, at Ferrassie, in Dordogne, a locality which has been made famous by the investigations of M. Peyrony during the past decade. Here he has discovered and studied five distinct layers, each containing the artifacts and animal remains of as many well-defined epochs. In ascending order these are:—(1) Acheulian, (2) Mousterian, (3) Lower Aurignacian, (4) Middle Aurignacian, and (5) Upper Aurignacian. The skeleton, which is described by Dr. Capitan in *La Nature* for December 25, 1909, was found between the layers 1 and 2, and as these and the three upper layers were absolutely intact, it is certain that the remains belong to the Mousterian epoch. The first bones seen were the ends of a tibia and femur, and before excavating further an invitation was sent to a number of French archæologists to witness the exhumation. With infinite care and precautions, an entire skeleton was revealed. It lay on its back, with the trunk turned slightly to the left; the legs were strongly flexed, the knees being turned to the right; the left arm was extended along the side, with the hand at the hip; the right arm was flexed, the hand being near the shoulder, and the head was turned to the left, the mouth being open.

The skeleton was photographed *in situ*. Around, above, and beneath were a large number of bones which had served as food for and had been broken by the Mousterians, as well as teeth of bisons, deer, goats and reindeer; the artifacts included points, knife-scrapers, disks, hammers, and bone-breakers of quartz of the Lower Mousterian type (that is, worked on one face only).

The long and small bones were carefully removed. The pelvis, thorax and skull were severally covered with tinfoil, and plaster was poured around each, so that when the plaster set they could be removed without injury. Thus protected, they were taken to Paris without further damage or loss. The restoration, mounting, and study of the skeleton are being undertaken by Dr. Capitan. As no anatomical details have as yet been given concerning the find, anthropologists will have to wait with what patience they can muster until the investigations are completed.

The attention of readers of NATURE has been directed at various times to the recent finds of Palæolithic man, but as this is the first whole skeleton which has been obtained of a Mousterian man, the discovery is one of prime importance.

There is no reason to doubt that the body was definitely placed where it was found; probably it was placed in a corner of a large rock shelter, and covered with earth, stones, and perhaps branches. The shelter was occupied later by generations of men of the Aurignacian epoch. Finally the overhanging chalk roof fell, and its débris subsequently became covered by a layer of stones and earth five feet in thickness. Thus protected, it has remained for 20,000 years.

A. C. H.

TROPICAL AGRICULTURE.[1]

THIS work does not claim to be a handbook for the technical man, but to give information of value to students, administrators, and others on tropical crops, and at the same time to present the political and theoretical aspects of the subject.

Part i. (pp. 1–39) deals with the "Preliminaries to Agriculture." Such topics as soil, climate, labour, transport, capital, supply of water, tools, and plant acclimatisation are briefly discussed, frequently by drawing contrasts between the less known conditions of the tropics and the better known conditions of temperate regions.

Part ii. (pp. 40–141), approximately half the volume, is devoted to the "Principal Cultivations of the Tropics." This is, in our opinion, the least satisfactory portion of the book. The principal industries of Ceylon, with which the author is closely acquainted, are well done. The accounts of rice, coffee, tea, cocoanuts, and Para rubber, are admirable, although for a work dealing with the tropics as a whole Ceylon looms larger than it should, and there is a tendency to ignore methods not practised there. Thus, in a general account of coffee, the "dry" method of preparation should certainly be described, considering the extent to which it is employed in Brazil, by far the greatest coffee-producing country. The Brazilian method of preparing Para rubber is not referred to. Similarly, very scanty attention is given to crops, *e.g.* maize, Guinea corn or sorghum, and cassava, to confine attention to food-stuffs which are very important over large areas of the tropics, although, it is true, but little grown in Ceylon. In some cases condensation has been carried so far as to render the account quite inadequate, and sometimes even misleading. To give one instance, in the chapter on rubber we find: "Lagos rubber, *Funtumia elastica*, has been a little planted in some of the British West Indian and West African colonies, but as yet no rubber has been exported." From this, the sole reference to this plant, no one would realise that the tree is wild over wide areas of West Africa, and yields large quantities of exported rubber, and, moreover, that it is also wild in Uganda, whence a moderate quantity of excellent rubber has recently come on the market.

---

[1] "Agriculture in the Tropics." An Elementary Treatise. By Dr. J. C Willis. Pp. xvii+222. (Cambridge: University Press, 1909.) Price 7s. 6d. net.

Striking examples of a lack of perspective are met with in the very brief notes on dyes and tans. In the former, after describing indigo and annatto, we find a list of "other dye stuffs of more or less local importance," in which occurs logwood! Cutch, from *Acacia Catechu*, is described as "perhaps the most important" of tanning substances, but why even in the brief list of other tans is there no mention of myrabolans (fruits of Terminalia, spp.)? Both are Indian tans, and in 1908, whilst the export of cutch was worth approximately 100,000*l*., that of myrabolans was nearly 400,000*l*. Several other similar instances might be quoted, and they detract considerably from what is otherwise a good, though somewhat restricted, survey of tropical agricultural industries.

Part iii., on "Agriculture in the Tropics (General)," and part iv., on the "Organisation of Agriculture," are distinctly interesting and valuable. They present the chief economic problems, including agricultural education and cooperative movements, with which the planters, administrative officers, and others have to deal, and suggest general lines along which the development of a tropical agricultural country should proceed to secure the best permanent advantage to both peasant and capitalist planter. These sections are well worth the careful study of all engaged in practically dealing with, or merely interested in, the broad administrative problems of the tropics. Such study should prevent much loss of time and money from misdirected efforts, and help to secure that continuity of policy without which even the best intentioned efforts come to naught. A book which presents these fundamental problems, and deals with them so well as Dr. Willis has done here, is a noteworthy addition to the literature of tropical agriculture.

Making Copra in Samoa. From "Agriculture in the Tropics."

REFORM OF THE CALENDAR.

SENOR C. A. HESSE, of Iquique, Peru, sends us an ingenious scheme for what he calls the reform of the calendar. It has, however, nothing to do with the Julian or Gregorian styles, or any modification of the latter, now used in all Christian countries except those of the Oriental Church, which still follow the Julian usage. But it is a plan, similar to one put forth in England a year or two ago, for making the days of the week and month correspond throughout the year. This he does by dividing the year into 13 months of 28 days (or 4 weeks) each; and as that would reduce the whole year to 364 days, he proposes two intercalations, one of a zero day, and another of what he calls a double zero day.

Plans of this kind would, if adopted, cause more trouble than they would save, besides interfering with the perpetual succession of the seventh day of the week. In endeavouring to adjust the ecclesiastical calendar according to his system, Señor Hesse gives at the end a table of the dates of the feasts in 1912 as now regulated and as proposed by him. They are, indeed, inadmissible. As to taking Easter a week later, that is of less consequence; but he puts Pentecost (Whit Sunday) 54 days after Easter and 13 days after Ascension Day!

It is to be hoped that some day the whole Christian church will come to an agreement to take Easter always on the first or second Sunday in April, adjusting the other movable feasts thereby. But as regards the days of the week and year, it would be a great mistake to tinker with them; and so-called zero days would produce most serious confusion.

It is a remarkable thing that the apocalyptic book of Enoch makes the year contain only 364 days, though it must have been known, according to any probable date of the composition of even its first part, that the integral number was 365. That, not being a multiple of 52, we must adjust the days of the week as we can. To increase the number of the months would be deplorable from many points of view. It would have been better if Julius Cæsar's first proposal about the respective lengths of the twelve months had been retained rather than the subsequent modification of Augustus; but to alter this now would give much more trouble than it would save. W. T. LYNN.

NOTES.

THE paper by Captain Tilho on the French mission to Lake Chad, which was read before the Royal Geographical Society on Monday evening, February 21, contained much interesting information about the hydrography of the Chad region. On arriving in the vicinity of the lake in 1908, the mission learned that caravans were crossing on dry land the northern portion of the lake-bed, where in 1904 Captain Tilho had navigated an open expanse of water; that the central portion was merely a marsh; but that in the southern portion channels which had formerly been closed to navigation had again become practicable. Summing up the results of the mission's investigations, Captain Tilho described Lake Chad as a closed depression about four-fifths the size of Belgium, entirely independent of the rivers that flow into the Atlantic and the Mediterranean. The average depth of the lake is 5 feet. Its shores are ill-defined, the slope being so slight that small variations in the level suffice either to submerge or to leave bare large areas of the lake-bed. Even the wind may produce these results. The waters of the lake are renewed for about a tenth part by the rainfall, and for about nine-tenths by the rivers that drain into the lake, principally the Shari and the Komadugu. Losses are due to evaporation and infiltration. In the present state of knowledge it is impossible to formulate a law governing the rise and fall of the lake, but there is no reason to suppose that it is likely to disappear. A problem which has exercised the minds of geographers is whether Lake Chad occupies the lowest part of the immense plain of which it is approximately the centre. The observations of the French mission show that to the north-east of the lake there is a series of plains of considerably lower altitude. The country falls about 200 feet in a distance of less than 250 miles.

THE Rev. G. F. Whidborne, who died on February 14, aged sixty-four, was an enthusiastic amateur geologist who endeared himself to a large circle of friends. Since 1876 he had been a Fellow of the Geological Society, and for many years, as a member of council, he took an active interest in the society's affairs. He was also a member of council of the Palæontographical Society, and was several times elected a vice-president. He was interested in many lines of geological research, but devoted himself especially to the study of fossil Invertebrata. In 1883 he contributed to the Geological Society's Journal a paper on new Mollusca from the Inferior Oolite, and between the years 1888 and 1898 he published three volumes on the Devonian fauna of the south of England, included in the monographs of the Palæontographical Society. In later years he was also attracted to more general questions, and became an active member of the Victoria Institute, to the journal of which he contributed two papers. Mr. Whidborne's genial presence was always welcomed at the scientific meetings he attended, and his memory will be cherished by all who had the good fortune to be associated with him.

THE late Mr. R. Marcus Gunn, the eminent ophthalmic surgeon, devoted much of the leisure of his vacations to making a collection of fossils, which he left to the British Museum (Natural History). He worked especially in the Jurassic formations of Sutherland, and at the time of his death was engaged in the preparation of a memoir on the Jurassic flora of Brora, in collaboration with Prof. A. C. Seward, who is now completing the undertaking. He obtained many fish-remains, Mollusca, and other fossils, which form a valuable addition to the national collection. Mr. Gunn also collected from the Old Red Sandstone of Caithness, and will always be remembered for his discovery of the problematical fossil fish *Palaeospondylus gunni*, which was named after him by Dr. Traquair.

THE following awards of the Mary Kingsley medal have been made by the Liverpool School of Tropical Medicine:—Mrs. Pinnock, in recognition of the services rendered to the cause of tropical medicine and sanitation by her brother, the late Sir Alfred Jones, founder and first chairman of the school; Mr. W. Adamson and Prof. W. Carter, for assistance rendered in the foundation of the school; Prince Auguste d'Arenberg, president of the Suez Canal Company, for his campaign against malaria at Ismailia; Sir William Macgregor, Governor of Queensland, for his services to sanitation and tropical medicine while Governor of Lagos; Surgeon-General Walter Wyman, head of the Marine Hospital Service of the United States, for the organisation which he has given to the service under him and for the manner in which he has always supported scientific principles in public sanitation; Sir Alfred Keogh, recently Director-General of the Royal Army Medical Corps, for the organisation which he has given to the service under him and for the manner in which he has always supported scientific principles in public sanitation. The medal for valuable contributions to the scientific and educational side of tropical medicine has been awarded to Prof. R. Blanchard, Paris; Dr. A. Breinl, director of the Tropical Diseases Institute in Queensland; Prof. A. Celli, Rome; Dr. C. W. Daniels, director of the London School of Tropical Medicine; Surgeon-Colonel King, Indian Medical Service; Prof. Nocht, director of the Hamburg School of Tropical Medicine; Prof. G. H. F. Nuttall, Quick professor of parasitology at Cambridge University; Major L. Rogers, Indian Medical Service; Prof. J. L. Todd, associate professor of parasitology at McGill University.

BY Colonel C. R. Conder's all too early death on February 16, science and geography have suffered a great loss. When still a young subaltern of engineers he was selected to continue the survey of the Holy Land under the auspices of the Palestine Exploration Fund, and he amply justified the selection. He had a natural aptitude for surveying, and he and his assistants made an excellent survey of a large area of the Holy Land. The difficulties he had to encounter were not confined to those incident to the survey of a rugged and unmapped country; to these were added troubles with Turkish officials and with the inhabitants; but his tact and genial nature, combined with the knowledge of the people and language he soon acquired, his energy and enthusiasm, triumphed over all obstacles, and enabled him to carry out the work in a manner which reflected credit on him and on his country. His service in Palestine affected the rest of Conder's life. A man of his ability and energy naturally did not confine himself to his technical survey work and to the identification of Biblical sites. He threw himself wholeheartedly into the many questions which arose in connection with this work, and applied to them a keen and ingenious intellect and an unbounded industry. The interests and studies which Conder first took up in Palestine were pursued by him to the end of a hard-working life. While in the army his official duties were often important and arduous, but he spent almost the whole of his spare time in study and literary work connected with the Holy Land, and after his retirement he devoted himself entirely to this work. Conder spent a good many years on the congenial work of the Ordnance Survey; he did good work on some of the other varied duties of the Royal Engineers, and later on under the Irish Government, but his name will be remembered mainly through his survey, his numerous books, and memoirs on the Holy Land. The views he propounded do not command universal acceptance, but they were based on hard and conscientious work, on deep study, and on intimate personal knowledge of the Holy Land, and his works have added largely to our knowledge.

CYCLONIC disturbances have for some time past continued to arrive from the Atlantic with more than usual frequency, and since the commencement of February the British Islands have been constantly under the influence of boisterous, warm, and moist south-westerly winds, which have blown from off the open ocean. Barometrical pressure has been uniformly lower in the northern part of our area than in the south. The central areas of the disturbances have passed either to the north of Iceland or between Iceland and Scotland. The storm systems became more thoroughly developed from about February 17, when a fairly severe gale was experienced in our northern and western districts. On Saturday, February 19, another important disturbance arrived from the Atlantic, and the barometer fell considerably below 29 inches over the greater part of the kingdom, accompanied by strong gales in many places. This disturbance was passing away to the north-eastward when a fresh fall of the barometer set in on our west coasts, resulting in a very severe storm over the whole country on Sunday. The barometer at 6 p.m. was as low as 28·1 inches in the north-west of Ireland, and the mercury was below 29 inches over nearly the whole of the British Islands. The barometrical gradient was very steep in Ireland and over the southern portion of England, and the heaviest winds were probably experienced in the English Channel and over the North Sea, where, from the estimated strength of the wind, the rate attained fully 70 or 80 miles an hour. The wind reached its maximum strength on Sunday afternoon and evening, and the gale was particularly gusty. At Greenwich the anemometer registered 30·7 lb. on the square foot at 8.55 p.m.; but this force was not of long duration, the maximum force at other times during the gale being only about 23 lb. on the square foot. The gale was, however, one of the strongest experienced in recent years, and much damage was done both on land and at sea, accompanied by serious loss of life. Thunderstorms occurred on the night of February 20 in parts of England, and the whole character of the weather was extremely unsettled. Detailed accounts of the absolute wind velocity for various parts of the United Kingdom have not yet been received at the Meteorological Office, but the records when to hand will prove both valuable and interesting.

THE following officers have been elected for 1910 in connection with the Paris Bureau des Longitudes: President, Prof. H. Poincaré; vice-president, M. G. Bigourdan; secretary, M. H. Deslandres.

AT the annual general meeting of the Physical Society, held on February 11, Prof. H. L. Callendar, F.R.S., was elected president for the ensuing year; and Prof. S. Arrhenius, Madame Curie, and Prof. G. E. Hale were elected honorary fellows of the society.

SIR WILLIAM PREECE, K.C.B., Sir Joseph Swan, and Prof. G. Vernon Harcourt have been elected the first honorary members of the Illuminating Engineering Society. The first anniversary dinner of the society was held on Thursday, February 10.

AT 6.38 a.m. on February 18 a sharp earthquake was felt at Canea (Crete). The shock was accompanied by a subterranean sound and an undulating movement lasting about fourteen seconds. Several buildings were damaged in Canea and the neighbouring country. Two slight shocks were felt at Malta on the same date shortly after 6.0 a.m.

MR. A. D. HALL, F.R.S., delivered, on February 22, the first "Masters" lectures, established by the Royal Horticultural Society in memory of the late Dr. M. T. Masters. His subject was the adaptation of the soil to the plant; and he described the factors which induce a particular plant to confine itself in nature to one special type of soil, or cause a given plant to flourish in one garden while failing in another.

WE learn from the *Times* that the inhabitants of Gross-Lichterfelde, the native place of Otto Lilienthal, have decided to erect a monument to the memory of their countryman, who was amongst the earliest practical pioneers in aviation, and met his death in 1896 while making a flight at Gömberg, in the province of Brandenburg. The monument will be erected either on the hill on the slopes of which Lilienthal made his early experiments, or in the square on the bank of the Teltour Canal.

THE anniversary meeting of the Geological Society was held on Friday, February 18, when the officers were elected as follows:—*President:* Prof. W. W. Watts, F.R.S. *Vice-presidents:* Dr. C. W. Andrews, F.R.S., Mr. A. Harker, F.R.S., Mr. W. Monckton, and Prof. W. J. Sollas, F.R.S. *Secretaries:* Prof. E. J. Garwood and Dr. A. Smith Woodward, F.R.S. *Foreign Secretary:* Sir Archibald Geikie, K.C.B., Pres.R.S. *Treasurer:* Dr. Aubrey Strahan, F.R.S. The following medals and funds were presented:—Wollaston medal to Prof. W. B. Scott; Murchison medal to Prof.

A. P. Coleman; Lyell medal to Dr. A. Vaughan; Wollaston fund to Mr. E. B. Bailey; Murchison fund to Mr. J. W. Stather; Lyell fund to Mr. F. R. Cowper Reed and Dr. Robert Broom. The president delivered his anniversary [illegible] which dealt with the antiquity of man.

[illegible] port of the council was presented at the annual [illegible] ral meeting of the Institution of Mechanical Engineers on February 18. Among other matters of interest dealt with we notice that a grant of 200*l.* was made towards the cost of depositing at the National Physical Laboratory a set of British standard Whitworth- and fine-thread hardened plug screw-gauges, with other screw-gauges and measuring machines. An exhaustive research into the properties of some alloys of copper, aluminium, and manganese was completed at the National Physical Laboratory in May by Dr. W. Rosenhain, in conjunction with Mr. F. C. A. H. Lantsberry. This forms the ninth report of the Alloys Research Committee, and is now before the Institution for discussion. In view of the extremely heavy task of completely investigating a ternary system of alloys, the committee, under the chairmanship of Sir William H. White, is now limiting its researches at the National Physical Laboratory to the study of light alloys of aluminium, and is dealing, in the first place, with those containing zinc or nickel. Prof. H. C. H. Carpenter is continuing at the University of Manchester his research, referred to in the last annual report, on the production of castings to withstand high hydraulic, steam, and gas pressure. A report is expected towards the end of 1910. The summer meeting of 1910 of the institution will take the form of a joint meeting in Birmingham and London with the American Society of Mechanical Engineers. This occasion will afford members an opportunity of reciprocating the hospitality extended to them in the United States during the joint meeting of 1904.

DR. A. M. MCALDOWIE read a paper before the Cotteswold Field Club on February 15 on field-notes on certain prehistoric remains near Cheltenham. The object of the paper was to show that many of the camps and barrows on the Cotteswold Hills, such as those of Leckhampton, Crickley, Coopers Hill, and others, were used in prehistoric times for observations of the rising and setting sun at the solstices and equinoxes. By the use of a series of diagrams he showed that the position of these monuments was in many cases in remarkable agreement with the solstitial lines. In the discussion which followed, the remarkable character of these coincidences was recognised, but the opinion was expressed that the suggestion that these camps and barrows were used for solar observations before they were utilised for purposes of protection and interment of the dead was improbable. The author referred to the curious custom of planting trees on barrows, possibly as homes for the spirits of the dead, and to the fact that a right of way very commonly was found to exist leading to the more important barrows, suggesting that they were scenes of assemblages for some religious purpose in early times.

WE have to welcome the first part of a new Yorkshire natural-history journal, in the form of the Proceedings, &c., of the Hull Junior Field Naturalists' Society. It contains a reprint of Mr. J. Ritchie's paper on the occurrence of the Arctic hydroid *Selaginopsis mirabilis* in British waters, and likewise of Mr. T. Sheppard's account of a specimen of the crustacean *Eryon antiquus* from the Yorkshire Lias.

To the February number of Witherby's *British Birds* [illegible] Fagan, secretary of the natural-history branch of the British Museum, communicates a full memoir, accompanied by an excellent portrait, of the late Dr. R. B. Sharpe. In the same issue Dr. N. F. Ticehurst records the occurrence of a pair of black wheatears, or black chats (*Saxicola leucura*), at Rye Harbour between August 31 and September 16, 1909, both of which were killed. This is the first record in Britain of this south European and north African bird.

WE have received a copy of the report of the Yorkshire Naturalists' Union for 1909, reprinted from the January number of the *Yorkshire Naturalist*, from which it may be gathered that the work of that body is being carried on as energetically as ever. We have been struck by the statement that Mr. J. F. Musham "sent a brood of young pipistrelles taken in a bedroom in the Northallerton district," since this would seem to imply (although it may bear another interpretation) that the pipistrelle may produce several young at a time. Information on this point would be of interest.

IN vol. iii., part iv., of Records of the Indian Museum, Dr. N. Annandale describes and figures, under the name of *Alaptus magnanimus*, what is apparently the smallest known insect, the length of the type-specimen being only 0·21 mm. and the wing-expanse 0·85 mm. The only known specimen made its appearance in the field of vision while its describer was engaged in observing under the microscope certain organisms in oil-of-cloves. It proved to belong to the hymenopterous family Myrmaridæ, and to be nearly allied to Westwood's *Alaptus excisus*. As the insect was unlikely to be met with by any professed student of the Hymenoptera, Dr. Annandale considered that he was not justified in neglecting the opportunity of publishing a description.

Two articles in the February number of the *Popular Science Monthly* are devoted to an account of modern work on marine biology and oceanography. In the first of these Prof. C. L. Edwards gives an illustrated description of the Swedish marine zoological station at Kristineberg, near the village of Fiskebäckshil, on the west coast. Fiskebäckshil was first brought into prominence as a promising situation for the study of marine biology in 1835, and four years later Sven Lovén and others joined the colony of naturalists who were then working with the meagre resources afforded by the place. In 1877 the Kristineberg station was founded by the Danish Royal Academy of Science at the initiation of Lovén, who became director, and held the post until 1892, when he was succeeded by his friend Hjalmar Théel. The second article, by Prof. C. A. Kofoid, is devoted to the Museum für Meereskunde at Berlin, which was opened in 1906, and is designed to illustrate everything connected with the sea and its products.

THE perennial discussion as to the homology of the columella auris in Amphibia is renewed in a lengthy memoir by Messrs. B. F. Kingsbury and H. D. Reed in the *Journal of Morphology* (vol. xx., No. 4, November, 1909). This memoir constitutes the second contribution of the authors' work on the columella auris in Amphibia, and deals with the Urodela, of which a large number of types have been studied by means of serial sections. It will probably be long before unanimity of opinion is arrived at on this difficult question, but it is satisfactory to those who have been brought up in the old faith that the columella auris of amphibians is homologous with the hyomandibular of fishes to learn that this view is supported by the present detailed investigation.

Apropos of the article on colour-blindness in Nature of January 27, Mr. C. R. Gibson has forwarded us a reprint on "An Occasional Peculiarity in My Own Colour Vision" (Royal Philosophical Society of Glasgow, 1908). On three occasions he has failed to distinguish brilliant red objects or light until the colour has been accidentally brought to his notice, when the colour appears immediately to flash into his consciousness, and he experiences a feeling of amazement that he could have been oblivious to it. There is every reason to believe that, as a rule, his colour vision is normal. If this is the case, we must conclude that there is a temporary block in the transmission of the nervous impulses from the periphery to the cortex of the brain, and that the position of the block is in the higher cerebral portion of the visual path. Bordley and Cushing have recently brought forward evidence of alterations in the field of vision for colours in cases of increased intracranial pressure due to cerebral tumours. The existence of a special cortical "centre" for the perception of colours is the subject of dispute. That there must be cortical representation of the impulses engendering colour perception is a point which need not be laboured. The problem is rather that of the dissociation, or the nature of the association, of the mechanism of colour perception with that of light and form perception in the higher levels of the brain. Evidence such as that brought to our notice by Mr. Gibson helps to elucidate this problem, though more definite evidence is obtained from cases such as one admirably reported by Dr. Edwin Bramwell in the *Review of Neurology and Psychiatry* for this month (vol. viii., February). Here a cerebral abscess secondary to bronchiectasis involved the cortex of the occipital lobe, and was accompanied by fits with a visual aura and by hemi-achromatopsia.

The production of rhizoid-like processes from cells of Spirogyra filaments when growing under unnatural conditions has been recorded by several observers from De Bary onwards. Evidence has tended towards the conclusion that these are malformations, and this opinion receives confirmation in a paper, by Dr. Z. Woycicki, which appears in the *Bulletin International de l'Académie des Sciences*, Cracow (October, 1909). In this case the ill effects are attributed to the gaseous atmosphere in the laboratory. A similar formation of rhizoids was induced in cultures of *Mougeotia genuflexa*, while the injection of gas into cultures of *Cladophora fracta* produced a crop of resting spores.

It is a debated point whether modifications in plants induced by special physiological conditions can be inherited or not, and a number of experimental investigations, chiefly with lower organisms, have been made with varying results. An account of experiments with *Aspergillus niger*, carried out by Mr. K. Kominami, is published as vol. xxvii., art. 5, of the Journal of the College of Science, Tokyo University. The fungus was grown for several generations in a strong (6 per cent.) solution of common salt, and the cultures so obtained were compared with the cultures raised in normal media. With regard to germination, the conidia of the modified stock started more rapidly and strongly than those from the normal plants, and this superiority was maintained throughout ten generations. On the contrary, modifications of the organism produced in poisonous solutions did not appear to be transmitted to succeeding generations.

In connection with a variety of plants which have been found to irritate the skin when handled by gardeners and others, Mr. J. H. Maiden, Government botanist for New South Wales, has commenced to collect and summarise evidence of authentic cases. In the *Agricultural Gazette of New South Wales* (December 2, 1909) Mr. Maiden deals with a number of plants—*Oenothera biennis*, L., *Hedera helix*, L., various Primulas, *Hyacinthus orientalis*, L., and varieties, *Thuja Douglasii*, *Agave americana*, and others—quoting specific instances of the irritation caused. He states that he has found literature relating to plants which irritate the skin—other than Rhus and Primula, which he dealt with in an earlier issue of the gazette referred to—exceedingly scarce or even wanting. Mr. Maiden would be glad of references or authoritative statements as to irritation or "poisoning" caused by any wild or cultivated plants.

In the *Bulletin International de l'Académie des Sciences de Cracovie* for November, 1909, appears a paper on the mineral alstonite, by Dr. Stefan Kreutz, in which he discusses the vexed question whether this substance is a double salt or an isomorphous mixture of the three members of the group, aragonite, witherite, and strontianite. From a careful consideration of his own and earlier observations he concludes that the second view is probably correct, but acknowledges some as yet inexplicable discrepancies. He explains the complex twinning either as simultaneous twinning about both {110} and {130} or as repeated twinning about {110}, as in the case of alexandrite.

Prof. A. Woeikof contributes an extremely interesting and suggestive study of the sources of human food-supply to *La Géographie* (vol. xx., Nos. 4 and 5, pp. 225 and 281). After pointing out that the substitution of any manufactured substance for vegetable food is extremely improbable, inasmuch as plant life is capable of storing solar energy in a much more economical manner than any machine, the author emphasises the facts that scarcely any one kind of food is universally regarded as a necessary of life, while many kinds which are now regarded as necessaries by certain peoples were almost unknown to them a few generations ago. From an examination of the geographical and economic conditions, Prof. Woeikof concludes that meat will in the future become so expensive as to be practically unavailable as an ordinary food, and that the supply must sooner or later be drawn wholly from the vegetable kingdom. He is of opinion that the application of scientific methods will increase the productiveness of the agricultural land of the world to an almost unlimited extent.

In the *Atti dei Lincei* (xix., 1), Dr. Umberto gives a short note on the solution of the hydrodynamical equations for two-dimensional steady motion in a region bounded by free stream lines, the remaining spaces being occupied by fluid at rest.

Under the title of "L'Énergie," a French translation of Prof. Ostwald's classical work has been added to the new scientific series published by M. Félix Alcan, Paris, under the editorship of Prof. Borel. The translator is M. E. Philippi, and the price is 3.50 francs.

From the *Annual Register* we learn that the American Mathematical Society now consists of 618 members, as against 601 at the beginning of last year. The library now contains nearly 3300 volumes, as against between one and two hundred nine years ago. The books can be borrowed through the post by members, and one of the aims of the library is to preserve as complete a record as possible of the growth of mathematics in America.

The *Revue générale des Sciences* (xx., 23) contains a second article, by Prof. Frédéric Houssay, on the form and stability of fishes. The author has now made models representing different kinds of fish, tapering to the tail end in the form of circular or elliptic cones, and fitted with fins and tails similar to those on the actual fishes. He finds that the short conical forms are the most stable, that stability is in every case secured by means of the fins, and that for certain limits of velocity an elongated conical form becomes unstable under the conditions existing in nature.

Many who have had experience of magnetic survey work on land, but have never attempted observations at sea, will be interested in an article, by Dr. L. A. Bauer, in the December (1909) number of *Terrestrial Magnetism and Atmospheric Electricity* on some problems of ocean magnetic work. It deals with the arrangements adopted on board the United States survey ship *Carnegie* by Dr. Bauer. Each of the three instrments in use is arranged to determine two of the magnetic elements, and the reductions are made within a few minutes of the observations being taken, so that if there is any disagreement repeat observations may be taken at once. Recording and reducing are in every way facilitated by the use of printed forms, and results are to be published rapidly. Thus Dr. Bauer intends to give a summary of the voyage ending January, 1910, in the March number of *Terrestrial Magnetism*, and future work is to be dealt with in the same prompt fashion.

We have received a separate copy of a paper on two mercury manometers for small pressures, by Drs. Karl Scheel and Wilhelm Heuse, of the Physikalisch-Technische Reichsanstalt, which appeared recently in the *Zeitschrift für Instrumentenkunde*. The first of the two manometers is a slight modification of the instrument described by Lord Rayleigh in 1901. A **U**-tube provided with a bulb on each limb is filled with mercury up to the middle of the bulbs. Just above each mercury surface is a fine glass point, an image of which can be seen in the mercury. The tube is attached to a support, which can be tilted about an axis perpendicular to the plane of the tube by means of a screw, while the angle of tilt is determined by the mirror and scale method, the mirror being attached to the support. The glass points and their images are observed through a microscope. To increase the range of the instrument, in the second form of it one of the bulbs can also be moved up or down on the support by means of a screw, and the movement measured by means of a second mirror supported partly on the fixed, partly on the moving, bulb. By means of the two instruments the authors have determined the vapour pressure of water at low temperatures to a high order of accuracy.

The existence of a negative coefficient of expansion for silver iodide, first demonstrated by Fizeau, and confirmed by Rodwell, has not yet been explained by any satisfactory hypothesis. Grinnell Jones (*Zeitschrift für physikalische Chemie*, January 25) suggests that Richard's hypothesis of compressible atoms may have a bearing on this point. From this point of view the volume change of a substance owing to a rise of temperature is the algebraical sum of the volume changes, the increase of the intramolecular space owing to the increased molecular vibration, the increase due to the diminution of cohesion, and a positive or negative volume change owing to an alteration in the mutual chemical attraction of the atoms. In the present paper it is shown that the affinity of silver and iodine increases with the temperature, and it is suggested that it is the resulting contraction which causes the negative expansion coefficient of silver iodide.

In view of the extreme fewness of the insoluble salts of sodium, exceptional interest attaches to the observations of Mr. W. C. Ball, as described in the Journal of the Chemical Society (December, 1909), to the effect that the nitrite $5Bi(NO_2)_3,9CsNO_2,6NaNO_2$ is substantially insoluble in water, whilst the corresponding potassium salt is soluble. The use of bismuth-cæsium-potassium nitrite provides a reagent by means of which small amounts of sodium may be detected and estimated in the presence of large quantities of potassium—a great advance on the indirect methods that have usually been employed. The reagent is made by dissolving 50 grams KNO_2 in 100 c.c. of water, neutralising with nitric acid, and adding 10 grams of powdered bismuth nitrate. To this liquid a 10 per cent. solution of cæsium nitrate is added until the sodium present in the KNO_2 has been precipitated; the solution is then filtered, and the cæsium salt added to a total of 2·5 grams. The method may be varied to detect cæsium by the use of bismuth sodium nitrite as a reagent, the precipitate having the same composition as in the previous case; rubidium may also be detected, but the test is less sensitive.

The problem of the best method of dumping stone, dirt, or other spoil into water is of particular interest in Stockholm, where rock-blasting and removal is being carried out continually for extensions to the harbour or to the streets. We learn from a note in *Engineering* for February 18 that a new form of automatic dumping apparatus has been designed and constructed by Mr. A. F. Wiking, of Stockholm. This self-dumping barge is built with a flush deck having low bulwarks on three sides, the fourth side being either left open or provided with doors which are opened by the pressure of the load on deck when the barge tilts over for dumping. The self-tilting of the barge is obtained by forcing water, by means of compressed air, into a cylindrical tank, which is carried on tripods at a height of about 16 feet above the deck. The admission of water to this tank upsets the stability of the barge, with the result that it tilts over and discharges its load. Arrangements are also provided for returning the water from the elevated tank after dumping is completed, so as to enable the barge to return to an even keel.

The large ice-making plant recently set to work at Grimsby by the Linde British Refrigerating Company, Ltd., is described in the *Engineer* for February 18. The plant is on the ammonia compression system, and consists of two steam-driven ammonia compressors, two belt-driven treble-ram water pumps, two ammonia condensers, two can ice-making tanks and brine refrigerators, centrifugal brine-circulating pumps, electrically driven cranes, ice crushers, and elevator. There is an insulated cold store of about 13,000 cubic feet capacity, and an ice store capable of holding 1100 tons of ice, both stores being cooled by means of pipes, through which cold brine is circulated by rotary pumps. The compression plant is driven by a Morley's patent cross-compound steam engine, designed to use highly superheated steam, and is provided with exceptionally large bearing surfaces, as it has to run six or seven months at a stretch without stopping. The results of trials show 9·56 lb. weight of steam per indicated horse-power per hour when producing 208 tons of ice per day of twenty-four hours; 5·12 lb. of ice were made per pound weight of steam The ice-making performance of the plant is about 41 tons of ice per ton of coal, a very creditable performance, which has not been approached by any other type of refrigerating machinery.

Messrs. Friedländer, of Berlin, have sent us copies of seven catalogues of scientific publications, devoted, respectively, to various branches of palæontology, geography, and physiography.

Messrs. Macmillan and Co., Ltd., have published the mathematical papers for admission into the Royal Military Academy and the Royal Military College for the years 1900–9 in a single volume, the price of which is 6*s*. The book has been edited by Messrs. E. J. Brooksmith and R. M. Milne, who have supplied answers to the questions.

A second edition of "Acetylene: the Principles of its Generation and Use," by Messrs. F. H. Leeds and W. J. Atkinson Butterfield, has been published by Messrs. Charles Griffin and Co., Ltd. The original issue of the work was reviewed fully in Nature of December 10, 1903 (vol. lxix., p. 122), and it will suffice to say that the book has been revised and enlarged, an appendix including descriptions of representative acetylene generators having been added.

The second part of "A Catalogue of Books on Natural History" has been issued by Mr. Bernard Quaritch, of Grafton Street, London, W. The present part completes the general works, and this section includes scientific voyages and transactions of learned societies; and the works on zoology are also begun. We notice that the section of the catalogue concerned with entomology includes two important libraries brought together by authorities on the subject. It is expected that the catalogue will be completed in ten parts.

The St. Catherine Press, Ltd., has published a handbook to the Scandinavian winter health resorts, written by Dr. T. N. Kelynack. The substance of the book originally appeared as a series of articles in the *Lancet*. The descriptions of places are written in a bright, interesting style, and indicate that Dr. Kelynack speaks from personal knowledge derived from direct inquiry and observation. Numerous illustrations add greatly to the attractiveness of the guide, which altogether should prove of value both to physicians and patients and to holiday seekers. The price of the book is 1*s*. net.

OUR ASTRONOMICAL COLUMN.

Discovery of a New Comet, 1910*b*.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by M. Pidoux at the Geneva Observatory. The position of the comet on February 20, at 7h. 10m. (Geneva M.T.), was R.A. = 0h. 46m. 22·1s., dec. = +7° 50′ 41″, and the daily motion was −2·4 m. in R.A. and −24′ in declination.

This position is in the constellation Pisces, the comet at the time of discovery being slightly east of north from δ, and a little north of west from ε, Piscium. Reference to the ephemeris for Halley's comet will show that, when discovered, this new object was apparently less than 1½° away from Halley's.

Comet 1910*a*.—The story of the discovery of comet 1910*a* is now exactly recorded, by Mr. Innes, in No. 4387 of the *Astronomische Nachrichten* (p. 311, February 12). It appears that the first intimation received by Mr. Innes arrived by a telephone message on January 15 from the *Leader*, a Johannesburg newspaper. This message stated that "Halley's comet was seen by Foreman Bourke, Driver Tricker and Guard Marais at 4h. 45m. rising in front of the sun. It was visible for about twenty minutes."

The next morning, Sunday, Messrs. Innes and Worssell kept watch, but clouds prevented an observation. The morning of January 17 was also cloudy, but there was a break just above the place of sunrise, and the comet was seen, at 5h. 29m. (standard time), by both observers independently, but by Mr. Worssell a few seconds the earlier; the telegram to Kiel was then dispatched.

Mr. Innes asks that, if seen by no one else earlier, it may be placed on record that this comet was first seen by railway officials at Kopjes, Orange Free State.

In the same number of the *Astronomische Nachrichten* Dr. Kobold gives the daily ephemeris, based on the improved elements, extended to March 12; the following is an extract:—

Ephemeris for 12h. (Berlin M.T.).

1910		α (1910·0) h. m.		δ (1910·0) ° ′		log *r*		log Δ		Mag.
Feb. 24	...	22 10·9	...	+11 55·6	...	0·05563	...	0·29959	...	5·4
28	...	22 14·6	...	+12 53·8	...	0·08681	...	0·31812	...	5·6
Mar. 4	...	22 18·1	...	+13 48·5	...	0·11505	...	0·33461	...	5·8
8	...	22 21·3	...	+14 40·5	..	0·14086	...	0·34936	...	6·0
12	...	22 24·3	...	+15 31·0	...	0·16463	...	0·36238	...	6·2

The magnitudes are based on the observation made by Prof. Hartwig on January 27 that the magnitude was then about 2·0, and by calculation the magnitude at perihelion becomes about −1·4. Observations made at Arcetri on February 7 gave corrections of +2s. and +0·4′ to the ephemeris places.

From this ephemeris we see that the comet is now apparently travelling, very slowly and in a direction slightly east of north, through Pegasus, and when it rises on the morning of March 3 it will be about 100′ north of 31 Pegasi, a fifth-magnitude star; but observations will be difficult owing to the apparent proximity of the sun.

The ephemeris also shows that the comet is retreating from the earth and sun at the rate of about two million miles per day, approximately in the direction of the earth-sun line; the present distances (February 24) are about 185 and 106 million miles respectively.

In No. 7 of the *Comptes rendus* (February 14, p. 369) M. E. Esclangon describes some remarkable transformations which he observed to take place in comet 1910*a* between January 22 and 30. On the former date the nucleus was about 15″ in diameter and very bright, and from each side of it, normally to the general direction of the tail, there appeared two currents of matter, nearly rectilinear near the source, but curving rapidly at some distance from it to form the tail. On January 30, however, the aspect was entirely changed, the nucleus being only 3″ or 4″ in diameter, and very sharply defined. The two currents of bright matter had been replaced by a circular nebulosity eccentric in regard to the nucleus; on February 9 no tail was visible. M. J. Comas Sola also communicates a paper dealing with the form of the comet, to which we hope to refer later. In a brief note M. Borrelly reports that on February 7 the comet was very faint, appearing fainter than stars of the eighth magnitude; on February 10 the magnitude was estimated as 8·5, and the comet was nearly circular, with a diameter of 2·5′.

Halley's Comet.—The following is a further extract from Mr. Crommelin's ephemeris as published in No. 4379 of the *Astronomische Nachrichten*:—

Ephemeris for Greenwich noon.

1910		R.A. h. m.		Decl. ° ′		log *r*		log Δ
March 1	...	0 34·0	...	+7 55	...	—	...	0·2774
6	...	0 30·2	...	+7 57	...	0·0397	...	0·2779
11	...	0 26·4	...	+8 0	...	—	...	0·2761
16	...	0 22·6	...	+8 2	...	9·9744	...	0·2711
21	...	0 18·5	...	+8 4	...	—	...	0·2623
26	...	0 14·2	...	+8 5	...	9·9017	...	0·2492
31	...	0 9·7	...	+8 4	...	—	...	0·2311
April 5	...	0 4·9	...	+8 1	...	9·8297	...	0·2069

These positions will be found plotted on the chart we gave in our issue of January 13 (No. 2098, p. 320), and during the greater part of April the comet will probably be unobservable. At present (February 24) the distances of the comet from the sun and from the earth are 116 and 175 million miles respectively, and the latter is increasing; but during the first week in March the earth and comet will again approach each other, until on March 31 the distance separating them will be but about 158 million miles.

In No. 419 of the *Observatory* (p. 105) Mr. Crommelin directs attention to the following parallelism of the election results of 1835 and 1910—both comet years—which is sufficiently remarkable to quote here:—

Parliaments of	...	1832	...	1906	...	1835	...	1910
Liberals ...	...	514	...	513	...	385	...	396
Opposition...	...	144	...	157	...	273	...	274

THE QUESTION OF "ABSORBING MATTER" IN SPACE.—In the January number of the *Astrophysical Journal* (vol. xxxi., No. 1, p. 8) Prof. Barnard discusses some of the "dark lanes," seen on a number of his beautiful photographs of nebulæ, from the point of view of their representing masses of actual absorbing matter. A nebulous region involving ν Scorpii is shown to be nearer than the general background of stars, and is at least partially transparent, but the absorption of the light of the stars behind it must be considerable, for it seems to show a distinct veiling tendency in certain regions. In the case of ρ Ophiuchi nebula, also, there are dark lanes which tempt Prof. Barnard to believe in the existence of opaque matter in the sky, although, if there is, it must be there, as shown on the photographs, on a gigantic scale. If it does exist, it is probably in connection, in some way, with nebulæ, for it is in nebulous regions that it is found. A magnificent photograph of the ρ Ophiuchi region is reproduced with the article, and Prof. Barnard believes that better photographs will show the nebulous region which he has photographed near π and δ Scorpii to be connected with the ν Scorpii and ρ Ophiuchi nebulosities.

PHOTOGRAPHIC OBSERVATIONS OF η AQUILÆ.—In No. 4385 of the *Astronomische Nachrichten* Herr A. Kohlschütter discusses a number of photographic observations of η Aquilæ made at Göttingen during 1906–7, and compares the results with those obtained from visual observations. This comparison shows that, essentially, the variability is the same photographically as visually, but the amplitude of the photographic variation is about 0·42 magnitude the greater.

EPHEMERIS FOR DANIEL'S COMET, 1909*e*.—A revised ephemeris for Daniel's comet (1909*e*) is given in No. 4387 of the *Astronomische Nachrichten*. Dr. Ebell, having been informed by Mr. Crommelin that the previous ephemeris, to which we directed attention last week, was incorrect, has calculated another, which he now publishes.

PRESENTATION TO SIR EDWARD THORPE, F.R.S.

AT the Government Laboratory on Friday, February 18, Sir Edward Thorpe was presented with a silver tea and coffee service and silver cigarette box subscribed for by former colleagues on the staff of the laboratory, and by members of other public departments intimately connected with the laboratory. Among the company present, besides Sir Edward and Lady Thorpe, were Sir George Murray, G.C.B., permanent secretary to the Treasury; Sir Thomas Elliott, K.C.B., secretary to the Board of Agriculture; Sir Nathaniel Highmore, Board of Customs and Excise; Mr. Middleton, Board of Agriculture; and Dr. J. J. Dobbie, principal of the Government Laboratory.

In making the presentation, Sir George Murray said he remembered being present at the opening of the Government Laboratory, and he had had ample opportunities of watching the progress of the department and the working out of what seemed in its inception to be a very novel and perhaps rather hazardous experiment. That experiment arose from a conviction that the demands of the Government on chemical science, as applied to the administrative business of government, could best be satisfied by a great central institution with an adequate equipment, and placed under the control of the most eminent man of science the Treasury could procure. The opposite idea was always dear to the hearts of departmental chiefs. They preferred a series of independent laboratories under their own control. From the moment of Sir Edward Thorpe's appointment, however, the laboratory gained the confidence of all the departments concerned, as well as of the public and the scientific world. He thought that the imposing variety of the work which was done in the laboratory could not fail to strike even the most uninstructed observer. The excellence of that work could be appreciated by only a very few.

Sir Thomas Elliott took this occasion of thanking Sir Edward Thorpe for the assistance, and more than the assistance, for the friendly advice and help that he had always shown himself ready to tender to the Board of Agriculture and Fisheries. Sir George Murray had referred to the relations between various departments, likening them to water-tight compartments. He, however, would compare them with so many foreign Powers treating with one another through the ordinary channels of diplomacy. He was sure that in overcoming such obstacles Sir Edward Thorpe showed the qualities of a statesman as well as those of a public official.

Mr. H. W. Davis, deputy principal, Mr. H. J. Helm, I.S.O., former deputy principal, and Mr. J. Connah, of the Customs branch of the laboratory, all referred to the excellent relations which had existed between Sir Edward and his colleagues, and to the great interest which Sir Edward had always taken in everything affecting the welfare of the laboratory staff.

Sir Edward Thorpe, in reply, said there was a large number of those present who could have very little conception of the difference between the old state of affairs at Somerset House and the new state in the Government Laboratory. The stars were favourable when he planned the new building, and he was glad to acknowledge the great assistance he received from individual members of his own department. The laboratory was planned, as all laboratories should be, from the inside outwards. He at once recognised that the removal from Somerset House to the new building was the opportunity for making new departures quite impossible to achieve under the old conditions. With the improvements possible in the new building, economies had been effected which practically repaid the cost of the building several times over. Sir Edward said that, apart from the routine work, several very important matters had devolved upon the laboratory which had taxed its energies to the utmost. One of the earliest arose out of the imposition of the sugar duties. The laboratory was obliged to carry out experiments upon the thermal expansion and specific gravities of glucose solutions of varying qualities, and to weld the results into tabular form. The arsenic poison scare, too, resulted in the elaboration of an apparatus for the rapid and accurate determination of infinitesimal quantities of arsenic. This apparatus had since come into official use in several countries besides our own. Further, at the present time the laboratory was, in amicable conjunction with the Brewers' Institute, engaged in a series of experiments with a view to the reconstruction and amendment of the tables upon which the method for determining the original gravity of beer is based.

A vote of thanks to Sir George Murray was proposed by Dr. Dobbie, and carried with acclamation.

BRILLIANT METEOR OF FEBRUARY 17.

ON February 17, at 6.8 p.m., a brilliant fireball was observed from various parts of the country. The evening twilight was strong, but the object created a very luminous effect; one observer, situated fully 250 miles from the meteor, estimated its light as quite three times as bright as Venus, and the streak or trail was visible for seven minutes.

Observations have come from the Thames near Sheerness, Guildford, Cardiff, and other places, and the radiant point appears to have been near Capella, from which a fine shower of February meteors is directed. The meteor was situated over Lundy Island or that region, and its height was probably from 88 to 46 miles, and velocity about 15 miles per second. As seen from Guildford, the streak remained on view nine minutes, when a cloud obscured it. It drifted far to the S.W. during its visibility, and it will be possible to compute the motion and direction of the drift very exactly.

More observations are required to define the real path with greater certainty, and amongst the large number of persons who saw the meteor it is hoped that some good records were obtained. The writer would be much interested in hearing some further particulars about the object, and especially with regard to its path in the heavens and place of the drifting streak. The meteor was probably the most brilliant observed in the British Isles hitherto this year.

W. F. DENNING.

THE HYDROGRAPHY OF THE NORTH SEA AND ADJACENT WATERS.

THE fourth report of the North Sea Fisheries Investigation Committee contains a number of papers on hydrographical researches in the northern part of the North Sea and the Færöe-Shetland channel which are of special interest, inasmuch as they provide a *résumé* of the work done since the committee began its labours, and a statement of certain results and conclusions which may now be accepted as definitely established and used as standards for comparison with future observations. These papers are:—(1) and (6) on hydrographical investigations in the North Sea and Færöe-Shetland channel during the years 1906–7–8, by Dr. A. J. Robertson; (2) on the temperature of the surface waters of the North Sea during the years 1906 and 1907, by Mr. Frank G. Young; (3) on the salinity of the North Sea, and (4) on surface-temperature observations between Hull and Hamburg during the years 1877–83, by Prof. D'Arcy Thompson; and (5) on the deep currents of the North Sea as ascertained by experiments with drift bottles, by Captain C. H. Brown. Dr. Robertson discusses the observations made during the periodic cruises executed by the SS. *Goldseeker* on lines laid down by the International Council. Mr. Young subjects to harmonic analysis temperature observations made by captains of passenger steamers and officers in charge of certain lightships and lighthouses. Prof. D'Arcy Thompson reviews in his first paper a long record of surface-temperature observations made between Hull and Hamburg by Captain W. Barron, and examines the relation of the sea temperature in the southern part of the North Sea to the air temperature of the adjacent coasts, and in his second paper gives an account of the mean values of salinity in the waters of the North Sea—the general distribution of salinity, its mean periodic variation, and the epochs of maximal and minimal salinity. Captain Brown reports upon experiments with the drift bottle devised by Mr. G. P. Bidder, which is so constructed as to float a few inches above the sea bottom, being carried along by the bottom current, and in the course of time scooped up by a trawl-net or found stranded on a beach.

In the summary which concludes his report on the observations of 1906, Dr. Robertson makes use of the results obtained by the other investigators, and lays down certain general rules. Tidal action is sufficiently active in the southern part of the North Sea to effect a thorough mixing of waters from surface to bottom; hence over this area, the northern boundary of which, by the way, seems somewhat uncertain in position, surface observations alone will henceforth be deemed sufficient. In the northern section the conditions are altogether different, and no uniformity exists in the surface to bottom distribution. Over the North Sea area the temperature decreases from the shore to the open sea in summer and increases in winter. In summer the warmest water (15° to 18° C.) occurs along the Belgian and Dutch coasts, and the coldest in the deep channel off Norway, while in winter the coldest water is, as a rule, along the Danish coast (2° to 3° C.), and the warmest between Scotland and Shetland (7° C.). The greatest annual variation at the surface occurs along the Belgian, Dutch, and German coasts, where it amounts to 13°, while between Scotland and Shetland it is some 9° less. In the deeper layers over the northern area of the North Sea the value is only 1°, while the smallest variation of all takes place in the deepest parts of the Skagerak, where it amounts to only 0·2°.

Mixing by tidal currents is so strong that water of less salinity than 33 per mille is rarely found more than a few miles from shore; over the North Sea area the variations in salinity are greatest at the surface, and the greatest mean deviation from the average occurs where salinity is lowest. In the northern area the variation seldom exceeds 0·2 per mille. The changes in salinity are thus too small to have any direct effect upon the occurrence or wanderings of food-fishes; they are mainly of interest as a guide in studying the movements of the waters.

Much information has been acquired with regard to the general circulation of the waters within the area, and the extent to which this undergoes changes of periodic and irregular kinds. Large volumes of Atlantic water are normally streaming northward as a surface current through the Færöe-Shetland channel into the Norwegian Sea, comparatively little entering the Norwegian Sea between Færöe and Iceland, where the east Iceland current comes southwards. Under exceptional conditions Polar water extends far enough south to enter the regions of the channel. (Dr. Robertson cites 1908 as one in which this occurrence was very well marked, and it was observed in 1902, as appears from Dr. Wolfenden's observations [*Geographical Journal*, April, 1903] and Dr. Robertson's report to the North Sea Committee, 1902–3 [p. 11]. The conditions observed by H.M.S. *Jackal* in 1893 were also probably somewhat similar.) The deeper layer north of the Wyville Thomson ridge is normally flooded with cold water of salinity 34·9 per mille, which is in direct connection with the bottom area of the Norwegian Sea, but in the southern parts of the channel at least these bottom layers are occasionally displaced by warmer and salter water, showing that marked changes may occur even at the greatest depths. (This also appears, from Dr. Wolfenden's observations, in the summer of 1900.)

Between the Færöes and Fair Isle the centre of the Atlantic stream is situated between 3° and 5° west longitude, where the mean annual temperature is 9·5° C. and salinity 35·29 per mille. Within the regions of the channel its direction of flow varies from north-east to east, and the speed of the surface waters apparently averages about fourteen miles in twenty-four hours. Branches are thrown off which enter the North Sea round the north and south of Shetland, and of these the latter is certainly subject to seasonal variation. A scanty winter salt-water distribution is normally followed by more vigorous inflow during early spring, increasing to a maximum in the beginning of summer, and gradually decreasing again on the approach of the following winter. As exceptional seasons, Dr. Robertson quotes (1) the winter 1905–6, when an unusually powerful Atlantic inflow took place; (2) the summer of 1907, when the maximum inflow was unduly delayed; and (3) the whole of 1908, when the inflow was very scanty.

The greater proportion of the Atlantic water entering the northern part of the North Sea area bends eastward before reaching the 57th parallel of latitude, and after throwing off a branch which enters the Skagerak as an undercurrent is carried back northwards. This rotational movement, due to the configuration of the bottom, gives rise to a cold, deep-water area, an area with a great temperature phase delay over which the maximum value in the bottom layers is not reached until near the close of the year. (This layer appears in the *Jackal* observations, 1893.) A fresh-water current continually streams northward along the Norwegian coast, being exclusively confined to the in-shore regions during the winter months, but extending in summer far out to sea as a thin surface layer; similar movements occur in summer off the Scottish coast.

From the above summary of Dr. Robertson's conclusions it appears that the normal distribution and circulation of the waters in the North Sea area may now be regarded as definitely known. The departures from the normal are, as was supposed, very considerable, but it would seem that the years 1905–6 and 1908 may be taken as representing the nature of the extreme variations which are likely to occur, and it is noteworthy that the older observations of H.M.S. *Jackal* and other vessels indicate conditions which, while showing some abnormal features for the years to which they refer, agree satisfactorily with the more recent and more adequate work as regards the type of distribution and general movement, and fall within the limits of departure from that type which they have themselves recorded.

H. N. Dickson.

THE THOMSEN MEMORIAL LECTURE.[1]

AMONG the Danes whose names are inscribed as men of science on the eternal bead-roll of fame, that of Julius Thomsen stands pre-eminent—linked indeed with that of Oersted. It is significant of the position which Thomsen acquired in physical science, and of the respect which that position secured for him in the eyes of his countrymen, that his statue should have been erected during his lifetime and placed in the vicinity of that of Oersted in the courtyard of the Polytechnic High School of Copenhagen. Thomsen, in fact, played many parts in the intellectual, industrial, and social development of Denmark. To Europe in general he was mainly known as a distinguished man of science. By his fellow-citizens he was further recognised as an educationist of high ideals, actuated by a strong common sense and a stern devotion to duty; as an able and sagacious administrator; as a successful technologist and the creator of an important and lucrative industry based upon his own discoveries; and as a man of forceful character, who brought his authority, skill, and knowledge of men and affairs to the service of the communal life of Copenhagen.

---

[1] Delivered before the Chemical Society on February 17, by Sir Edward Thorpe, C.B., F.R.S., past-president of the Society.

Thomsen was a municipal councillor of that city for more than a third of a century. He occupied a commanding position on the Council, and was invariably listened to with respect. The gas, water, and sewage works of Copenhagen are among the monuments to his civic activity. From 1882 up to the time of his death he was a member of the Harbour Board of the port. In these respects Thomsen sought to realise Priestley's ideal of the perfect man—that he should be a good citizen first and a man of science afterwards.

Hans Peter Jürgen Julius Thomsen was born in Copenhagen on February 16, 1826. He was educated at the church school of St. Peter in that city, and subsequently at von Westens Institute. In 1843 he commenced his studies at the Polytechnic, and in 1846 graduated there in applied science, and became an assistant to Prof. E. A. Scharling. Of his earliest years comparatively little is known. Thomsen, always a reserved and taciturn man, talked little about himself even to his intimate friends—and least of all about the days of his youth. It was known to a few that these days had not been smooth. Those who were best informed were conscious that to these early struggles much of that dour and resolute nature which formed a distinguishing trait in his character was due. Thomsen, indeed, began life as a fighter, and a fighter he remained to the end of his four-score years.

In 1847, he became assistant to Forchhammer, passing rich, like Goldsmith's pedagogue, on 40*l.* a year. Georg Forchhammer, whose earliest work dates back to the period when Berzelius was in his prime, was an active and industrious investigator of the old school, mainly in inorganic chemistry, and more particularly on problems of chemical geology and physiography. He was a frequent visitor to this country, and was well known to early members of the British Association. Although doubtless influenced, in common with all teachers in northern Europe, by the example and methods of Berzelius, such influence as he himself was able to exert died with him. Forchhammer attracted few pupils, and created no school, and Thomsen probably derived no inspiration or acquired any stimulus from this association. For a time Thomsen supplemented his scanty income by teaching agricultural chemistry at the Polytechnic. In 1853 he obtained a travelling scholarship, and spent a year in visiting German and French laboratories. He probably owed this scholarship in great measure to his first contribution to the literature of chemistry, namely, his memoir, "Bidrag til en Thermochemisk System" (contributions to a thermochemical system), communicated to the Royal Society of Sciences of Copenhagen in 1852, and for which he received the silver medal of the society and a sum of ten guineas to enable him to procure a more accurate apparatus. In this memoir he sought to develop the chemical side of the mechanical theory of heat, doubtless under the influence of Ludwig Augustus Colding, an engineer in the service of the Municipality of Copenhagen, and a pioneer, like Mayer, in the development of that theory. Indeed, the Danes now claim for Colding, who had made experiments on the relation between work and heat as far back as 1842, but whose labours were practically ignored by his contemporaries, the position which the Germans assign to Mayer (see Mach's "Development of the Theory of Heat"). In 1861 Thomsen further developed his ideas in a memoir on the "General Nature of Chemical Processes, and on a Theory of Affinity Based Thereon," published in the Transactions of the Danish Academy of Sciences. In this paper he laid the foundations of the chief scientific work of his life.

In 1853 Thomsen patented a method of obtaining soda from cryolite, so-called "Greenland," or ice-spar, a naturally occurring fluoride of sodium and aluminium, $Al_2F_6,6NaF$, found largely, indeed, almost exclusively, in Greenland, and particularly at Ivigtut. It derives its mineralogical name from its ice-like appearance and ready fusibility even in the flame of a candle. It seems to have been first brought to Europe in 1794, and to have been described by Schumacher in the following year. Klaproth first showed that it contained soda, and its composition was further established by Vauquelin, Berzelius, and Deville.

Thomsen's process consists in heating a finely divided mixture of cryolite and chalk in a reverberatory furnace, whereby carbon dioxide is expelled and calcium fluoride and sodium aluminate are formed. The roasted mass is lixiviated with water, so as to dissolve out the sodium aluminate, which is then treated with carbon dioxide. Alumina is precipitated, and sodium carbonate remains in solution. The alumina is either sold as such or converted into sulphate (co-called "concentrated alum" or "alum-cake"), and the sodium carbonate is separated by crystallisation. Both products are obtained in a remarkably pure condition, and the cryolite-soda yields excellent "caustic."

Thomsen's process, although simple enough in principle, requires considerable skill and pains in its practical execution, and most of the manufacturing details were worked out by him, or under his direction. Success largely depends upon the maintenance of a proper temperature; the decomposition begins below a red-heat, but requires to be finished at that temperature, and care must be taken to avoid fusion or even sintering of the mass. In 1854 Thomsen obtained the exclusive right of mining for cryolite and of working up the mineral in Denmark for soda and alumina. Actual manufacturing operations were begun on a small scale in 1857, and in the following year Thomsen planned the present large factory at Oeresund, near Copenhagen, which was opened on his thirty-fourth birthday. The importance of this industry to Denmark may be seen from the circumstance that during the fifty years of its existence the firm have paid the Danish Government nearly 300,000*l.* for the concession. Other factories were started in Germany, Bohemia, and Poland, but met with little success. The Pennsylvania Salt-manufacturing Company at Natrona, near Pittsburg, eventually obtained the right to work up two-thirds of all the cryolite mined in Greenland. From the start Thomsen took a large share in the management of the Oeresund works, and by his energy, foresight, and skill placed the undertaking on a sound commercial basis.

Although Thomsen died a rich man, mainly as the result of the industry he created, in the outset of his career as a teacher and a technologist his means were very straitened. He came of poor parents, of no social position or influence, and they were unable to further his inclinations towards an academical career. In 1854 he applied unsuccessfully for a position as teacher of chemistry at the Military High School in Copenhagen. During three years—from 1856 to 1859—while still engaged in developing his cryolite process, he acted as an adjuster of weights and measures to the Municipality of Copenhagen. It was a poorly paid position, but it kept the wolf from the door. At about this period he betook himself to literature, and published a popular book on general subjects connected with physics and chemistry—somewhat in the style of Helmholtz's well-known work—entitled "Travels in Scientific Regions," which had a considerable measure of success. He was, however, not altogether unknown even at this time as an author, since in 1853 he had collaborated with his friend Colding in producing a memoir on the causes of the spread of cholera and on the methods of prevention, which attracted much attention at the time of its appearance.

In 1859, whilst engaged in the Oeresund factory, he again applied to the authorities for a position as teacher at the Military High School, and succeeded in obtaining an appointment to a lectureship in physics, which he held until 1866. During his tenure of this office he devised his polarisation battery, which received many awards at international exhibitions and was used for a time in the Danish telegraph service.

In 1859–60 he was "vicarius" for Scharling at the University, and in 1865 became a teacher, and in the following year professor of chemistry and director of the

Chemical Laboratory, a position which he retained—active to the last—until 1901, when he retired in his seventy-fifth year of age.

Before his connection with the University, he founded and edited, from 1862 to 1878, in association with his brother, August Thomsen, the *Journal of Chemistry and Physics*, one of the principal organs of scientific literature in Denmark.

In 1863 he was elected a member of the Commission of Weights and Measures, and was instrumental in bringing about the adoption of the metric system and the assimilation of the Danish system to that of the Scandinavian Kingdom.

In 1883 Thomsen became Chancellor of the Polytechnic High School of Copenhagen—a position which he held for about nine years. During this period he entirely changed the character and spirit of the school, and stamped it with the impress of his earnestness and industry. Under his direction, new buildings were erected and arranged in accordance with the best Continental and American models. Thomsen's administration was in marked contrast to that of his somewhat easy-going predecessor, but it is doubtful if it brought him popularity in the school. The students respected and even feared him, but his cold and unsympathetic nature evoked no warmer feeling. It was said of him by one who knew him intimately that he never learned to draw the young to him, to create in them an interest for his work, to form a school. Thomsen was a homely man, but not even in his home, says the same authority, was it possible for him to change his active, earnest, strenuous disposition—what his friends called his fighting character. But if he was always the serious master of the house, he was also its obedient servant. In reality he was a man of deep feeling, and was not without power to give that feeling expression in words, sometimes in verse, and occasionally even in music.

It was while occupying the position of director of the chemical laboratory of the University that Thomsen executed the thermochemical investigations which constitute the experimental development of the ideas he had formulated in his memoir of 1861. The results of these inquiries were first made known in a series of papers published from 1869 to 1873 in the Transactions of the Royal Danish Society of Sciences, and from 1873 onwards by the *Journal für Praktische Chemie*. The papers were republished in collected form in four volumes (1882–1886) by a Leipzig house under the title of "Thermochemische Untersuchungen." A summary of this experimental labour, which extended over a third of a century, was subsequently prepared by Thomsen, and published in 1905 in Danish under the title of "Thermokemiske Resultater."

In this work he reviewed the whole of the numerical and theoretical results, to the exclusion of the greater portion of the experimental details. A translation of this volume by Miss Katharine A. Burke, entitled "Thermochemistry," renders it readily accessible to English readers. Miss Burke has supplemented the original work by a short account, taken from the "Thermochemische Untersuchungen," of the experimental methods employed, thereby rendering the whole more intelligible to the student. Moreover, in the English edition a partial attempt has been made to translate Thomsen's deductions into the language of modern theory based on the conception of ionisation, which, of course, was not known to science at the time the "Thermochemische Untersuchungen" was published.

It is impossible within the limits of such a notice as this to deal in detail with the immense mass of experimental material which this work embodies, and I shall not attempt, therefore, to do more than to offer a generalised statement, based mainly upon the admirable account of Thomsen's work given by Prof. Brönsted to the Chemical Society of Copenhagen on the occasion of the meeting held on March 2, 1909, to commemorate Thomsen's services to science.

The conception of affinity as a cause and determining condition of chemical change is traceable in some of the earliest efforts to coordinate and explain chemical phenomena. It certainly existed long prior to the time of Boyle, and was at the basis of every philosophical system after his period. We need only mention the names of Bergman, Wenzel, and Berthollet to indicate this fact. But to Thomsen belongs the credit of being the first to make the attempt to measure the relative value or strength of affinity quantitatively, and to express it numerically in definite terms which admitted of exact comparison. Thomsen's theory of affinity, as enunciated by him in his 1851 paper, was based upon his conviction that affinity could be measured quantitatively by estimating the amount of heat evolved in the chemical process. We are not immediately concerned to show whether the theory is right or wrong, or in what respect it fails. The point is that the enunciation of this principle upwards of half a century ago constituted an important step forward, inasmuch as it sought to estimate affinity in relation to a quantity which can be fixed by experiment, and is capable of expression by numbers. In this and in the subsequent paper of which mention has been made already, he thus defines his conception of thermochemistry, and discusses, for the first time, its laws.

"The force which unites the component parts of a chemical compound is called affinity. If a compound is split up, whether by the influence of electricity, heat, or light, or by the addition of another substance, this affinity must be overcome. A certain force is required the amount of which depends on the strength of the affinity.

"If we imagine, on the one side, a compound split up into its component parts, and on the other side these parts again united to form the original compound, then we have two opposite processes the beginning and end of which are alike. It is therefore evident that the amount of the force required to split up a certain compound must be the same as that which is evolved if the compound in question is again formed from its component parts.

"The amount of force evolved by the formation of a compound can be measured in absolute terms; it is equal to the amount of heat evolved by the formation of the compound.

"Every simple or complex action of a purely chemical nature is accompanied by evolution of heat.

"By considering the amount of heat evolved by the formation of a chemical compound as a measure of the affinity, as a measrue of the work required to again resolve the compound into its component parts, it must be possible to deduce general laws for the chemical processes, and to exchange the old theory of affinity, resting on an uncertain foundation, for a new one, resting on the sure foundation of numerical values."

As has been proved by later theoretical and experimental investigations, the theory of thermochemical affinity is not absolutely correct at ordinary temperatures. But, on the other hand, it has been shown that a comparatively large number of processes are approximately in unison with it. Not only do they agree qualitatively, that is to say, that heat is evolved during the process, but also in the fact that the results which newer and more exact methods for estimating affinity have produced agree numerically with what would be required by the thermochemical theory. We meet here with a fundamental phenomenon which Thomsen deserves great credit for having first pointed out, but the explanation of which could not be given at the time he indicated it. It can be demonstrated theoretically that the lower we reduce the temperature and the nearer we get to the absolute zero, the more nearly is the condition for the theory fulfilled, so that at the absolute zero the theory would be found to be an exact law of nature. If it were possible to work at such low temperatures it would be found that the evolution of heat, or the evolution of energy by the chemical process, would be an exact measure of the affinity of the process and that under this condition the theory of Thomsen would be the accurate expression of a natural law.

But under ordinary conditions this is not so, for in reality an ever-increasing number of endothermic processes are found to occur, that is, processes which proceed with the absorption of heat. Thomsen tried at first to explain these phenomena in such a way as to keep them within his system, and he drew a distinction between a purely chemical process running conformably to his theory and a physico-chemical process which did not fall within the law. But he was gradually convinced that his theory could not be maintained in its entirety. It is to his credit that he did not seek to uphold an untenable principle, or try to defend it as did Berthelot, who almost to his dying day maintained the validity of the principle in spite of all facts.

These ideas have, in the words of Ostwald, been the scientific confession of faith of chemists throughout half a century. They have had the greatest influence on scientific thought in every branch of chemistry. It is on the basis of them that we have arrived at a theory of affinity which at the present moment is being developed into one of the most perfect chemical theories. Lastly, it is due to these ideas that the experimental material has been produced which during all time will place the name of Julius Thomsen in the first rank of men of science.

To go through this material in detail is, as I have said, impossible here. It may be stated generally that practically every simple inorganic process has been investigated calorimetrically by Thomsen, or can be calculated by means of the calorimetric data furnished by him. In the case of organic substances, data have been given for estimating the heat of combustion of a large number of compounds. All these estimations were made by Thomsen personally, according to a pre-arranged plan, and in systematic succession during a period of more than thirty years. They comprise more than 3500 calorimetrical estimations. It has been truly said that this work is unique in the chemical history of any country.

Among the results of Thomsen's thermochemical inquiries which have special value for physical chemistry is his investigation of the phenomena of neutralisation, in which he shows that the basicity of acids can be estimated thermochemically, and that it can in this way be proved whether or not a point of neutrality exists. His observation that the heat of neutralisation is the same for a long series of inorganic acids, such as hydrochloric acid, hydrobromic acid, hydriodic acid, chloric acid, nitric acid, &c., supports the theory of electrical dissociation, inasmuch as this requires that the heat of neutralisation of the strong acids must in all cases be independent of the nature of the acid, because the process of neutralisation for all of them is the combination of the ion of hydrogen in the acid with the ion of hydroxyl of the base to form water. These investigations also led to the important thermochemical result that the heat of neutralisation of acids (or the heat of their dissociation) cannot be considered as a measure of the strength of the acids.

Another important result is the proof by experiment of the connection which exists between the changes of the heat-effect with the temperature and the specific heat of the reacting substances. The first law of thermodynamics requires the relation indicated by Kirchhoff: $dU/dT = C_1 - C_2$, where U is the heat-effect, T the temperature, and C_1 and C_2 are the heat capacities of the two systems before and after the reaction, and Thomsen showed by investigation of the heat of neutralisation, the heat of solution, and the heat of dilution, that this relation was satisfied. For the purpose of his inquiry, the specific heats of a large number of solutions of salts were estimated by an ingenious method, and with an exactness hitherto unattained.

Of no less importance are Thomsen's thermochemical investigations on the influence of mass. In the year 1867 Guldberg and Waage published their theory of the chemical effect of mass. But they had only verified the theory to a small extent and in particularly simple cases. They had not investigated the complete homogeneous equilibrium, because at that time no method existed for experimental investigation of such homogeneous equilibrium. Thomsen showed that the estimation could be made thermochemically. By allowing, for instance, an acid to act on a salt of another acid in an aqueous solution, the latter acid will be partly replaced by the first, which will form a salt. By mixing, for instance, a solution of sodium sulphate and nitric acid, there is formed sodium nitrate and sulphuric acid, but the process will not proceed to completion. If we have estimated the heat of neutralisation of the two acids with sodium hydroxide, the difference between these two heat-phenomena will give the amount of heat corresponding to the total decomposition of the sodium sulphate, and the heat found experimentally by mixing the two solutions will therefore show to what degree the transformation has taken place. It would be possible to estimate thermochemically the amount of the four substances in solution, and thereby, by varying the concentration or the proportion between the initial quantities of substances, to calculate whether the Guldberg-Waage theory on the effect of mass was confirmed in this case.

Thomsen applied this method to a large number of different acids and bases, and was enabled thereby to prove the agreement with the law of the influence of mass in all the cases which he examined. He found particularly that the proportion of the one acid which remained combined with the base was constant with mixtures of constant proportion. On this basis he propounded the term *avidity*, which he defined as the tendency of the acid to unite with the base, and he showed that the avidity was independent of the concentration, and only to a small extent varied with the temperature. The term avidity has since acquired great importance, particularly since other and more exact methods for its estimation have been found. Concurrently with this, its meaning has been made clear by the theory of electrolytic dissociation.

On the basis of these estimations, Thomsen drew up the first table, based on experiments, of the relative strength of the acids, and the numbers in this table have been found to agree with the results obtained by examining the electrical conductivity of the acids.

It is worth noting that Thomsen not only produced the experimental proof of the correctness of the Guldberg-Waage theory of the effect of mass soon after the appearance of this theory, but also that he was the first to acknowledge and adopt it. It is remarkable that this work of Thomsen received so little attention, although it appeared in a widely circulated German journal, and it was not until ten years later that the law of the effect of mass was generally recognised, as the result of the work of Ostwald and van 't Hoff.

Although Thomsen's title to scientific fame rests mainly upon his thermochemical work, his interests extended beyond this particular department of physical chemistry. He worked on chloral hydrate, selenic acid on ammoniacal platinum compounds, and on glucinum platinum chloride, on iodic acid and periodic acid, on hydrogen peroxide, hypophosphorous acid, and hydrogenium. He early recognised the importance of Mendeléeff's great generalisation, and contributed to the abundant literature it produced. His paper of 1895, "On the Probability of the Existence of a Group of Inactive Elements," may be said to have foreshadowed the discovery of the congeners of argon. He pointed out that in periodic functions the change from negative to positive value, or the reverse, can only take place by a passage through zero or through infinity; in the first case, the change is gradual, and in the second case it is sudden. The first case corresponds with the gradual change in electrical character with rising atomic weight in the separate series of the periodic system, and the second case corresponds with a passage from one series to the next. It therefore appears that the passage from one series to the next in the periodic system should take place through an element which is electrically indifferent. The valency of such an element would be zero, and therefore in this respect also it would represent a transitional stage in the passage from the univalent electronegative elements of the seventh to the univalent electropositive elements of the first group. This indicates the possible existence of a group of inactive elements with the atomic weights 4, 20, 36, 84, 132, the first five numbers corresponding fairly closely with the atomic weights respectively of helium, neon, argon, krypton, and xenon (*Zeitsch. anorg. Chem.*, 1895, ix., 283; Journ. Chem. Soc., 1896, lxx., ii., 16). He subsequently made known the existence of helium in the red fluorite from Ivigtut.

As evidence of Thomsen's manipulative ability and his power of accurate work may be mentioned his determination of the atomic weights of oxygen and hydrogen, and incidentally of aluminium. For the atomic weight of hydrogen he obtained the value 1·00825 when O=16, which is practically identical with that of Morley and Noyes. He further made most accurate estimations of the relative densities of these gases, and of the volumetric ratios in which they enter into the composition of water. His value for the atomic weight of aluminium is nearly identical with that adopted in the last Report of the International Committee on Atomic Weights.

Thomsen maintained his interest in thermochemical problems up to the end, and was a keen and clear-sighted critic of the work which appeared from time to time during the later years of his life. This interest occasionally gave rise to controversy, and some of his latest papers were wholly polemical.

Thomsen was a pronounced atomist, and to him a chemical process was a change in the internal structure of a molecule, and the chief aim of chemistry was to investigate the laws which control the union of atoms and molecules during the chemical process. He considered that chemistry should be treated mathematically as a branch of rational mechanics. But no one insisted more strongly than he how little we really know of these questions. In summarising his theoretical ideas in the *Thermokemische Resultater,* he says, "An almost impenetrable darkness hides from us the inner structure of molecules and the true nature of atoms. We know only the relative number of atoms within the molecule, their mass, and the existence of certain groups of atoms or radicles in the molecule, but with regard to the forces acting within the molecules and causing their formation or destruction our knowledge is still exceedingly limited." He fully realised that his own work was only the foundation on which the future elucidation of these questions must rest. "He worked," says Brönsted, "in the conviction that what we somewhat vaguely call the affinity of the atoms—their interaction, their attraction, and varying effect, &c.—follows the general laws of mechanics, and that, as he worded it, the principle that 'might is right,' holds good in chemistry as in mechanics. On this foundation he hoped to be able to evolve the laws for the statics and dynamics of chemical phenomena, even although the true nature of the action is unknown."

Thomsen's merits as an investigator received formal recognition from nearly every country in the civilised world. So far back as 1860 he was elected one of the thirty-five members of the Danish Royal Society of Sciences of Copenhagen, and from 1888 until his death he was its president. In 1876 he became an honorary foreign member of the Chemical Society of London. On the occasion of the fourth centenary of the foundation of the University of Upsala (created in 1477), he received the degree of Doctor of Philosophy *honoris causa.* In 1879 he was made an honorary M.D. of the University of Copenhagen. Two years later he was made a foreign member of the Physiographical Society of Lund, and in 1888 he was elected a member of the Society of Science and Literature of Gothenburg. In 1885 he became a member of the Royal Society of Sciences of Upsala, and in 1886 of the Stockholm Academy of Sciences.

In 1883 he and Berthelot were together awarded the Davy Medal of the Royal Society—a fitting and impartial recognition on the part of the society of the manner in which the two investigators, whose work not infrequently brought them into active opposition, had jointly and severally contributed to lay the foundations of thermochemistry.

In the same year Thomsen was made a member of the Accademia dei Lincei of Rome, and in the following year he was elected into the American Academy of Arts and Sciences in Boston, and of the Royal Academy of Sciences of Turin. In 1887 he was made a member of the Royal Belgian Academy.

In 1886–7, and again in 1891–2, he was rector of the University of Copenhagen. In 1888 he became Commander of the Dannebrog, and in 1896, and on his seventieth birthday, he was made Grand Commander of the same order. On the same occasion the Danish chemists caused a gold medal to be struck in his honour. In 1902 he became a Privy Councillor (Geheime Konferenz raad). In the same year he was elected a foreign member of the Royal Society of London.

He died on February 13, 1908, full of years as of honours, and was buried on the eighty-third anniversary of his birth and on the jubilee of the opening of the Oeresund factory. His wife, Elmine Hansen—the daughter of a farmer on Langeland—predeceased him in 1890.

I desire to express my acknowledgments to Director G. A. Hagemann, of Copenhagen, and to Prof. Arrhenius, of Stockholm, for their assistance in obtaining information concerning Thomsen's personal history. I am also much indebted to our fellow, Mr. Harald Faber, for his kindness in making for me a translation of Prof. Brönsted's account of Thomsen's scientific work, on which my own *résumé* is mainly based.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Sir J. J. Thomson has been nominated to represent the University at the celebration next October of the centenary of the University of Berlin.

Mr. S. Brodetsky, bracketted senior wrangler in 1908, has been elected to the Isaac Newton studentship, tenable for three years.

The adjudicators of the Smith's prizes and Rayleigh prizes are of opinion that the following essay sent in by a candidate is of distinction, "Discontinuous Motion in Gases," by Mr. G. I. Taylor. A Smith's prize is awarded to Mr. Taylor for this essay. The second Smith's prize is not awarded.

In response to an appeal for funds for the purpose of purchasing a site and for building, equipping, and conducting a field laboratory on the outskirts of Cambridge, mainly for the study of protozoal and parasitic diseases, donations amounting to 988*l.* 17*s.* have been received. A donation of 1000*l.* has been promised, anonymously, when the fund has reached 6000*l.* In addition to the foregoing, the Government of Cape Colony has placed the sum of 500*l.* at the disposal of Prof. Nuttall for the purpose of investigating East Coast fever. By permission of the Government, a part of this sum will be utilised for the construction of the laboratory.

OXFORD.—The fact that Halley occupied the Savilian chair of astronomy at Oxford gives this University a special interest in Halley's comet. This interest the University proposes to mark by conferring the honorary degree of Doctor of Science on Mr. P. H. Cowell, F.R.S., chief assistant, and Mr. A. C. D. Crommelin, assistant, at the Royal Observatory, Greenwich, by whose joint calculations the exact determination of the re-appearance of Halley's comet was successfully accomplished. The actual ceremony of conferring the degree will probably take place in May, at the time when the comet is expected to be at its brightest. It has further been arranged that the first discourse given on the new foundation of the Halley lecture shall be delivered by the founder himself, Dr. Henry Wilde, F.R.S., and it is hoped that this may take place at the same time as the conferring of degrees on the two Greenwich astronomers.

ST. ANDREWS.—Besides the munificent gifts to the chemical department of the University already noted, Dr. Purdie recently handed 2000*l.* to the University Court to aid in paying a chemical assistant.

Prof. Percy Herring (physiology) has been appointed dean of the faculty of science, and he enters on his duties at the end of the winter session, the pro-dean (Prof. Butler) meanwhile officiating during the enforced retirement of Prof. Musgrove from illness.

The spacious new Pettigrew Museum of Natural History (the gift of Mrs. Pettigrew) is approaching completion, and the hothouses and conservatories in connection with the botanical department, to which Mrs. Pettigrew also liberally contributed, are well advanced.

A JOINT conference of members of the Geographical Association and of the Federated Associations of London Non-primary Teachers will be held at 3 p.m. on Saturday, March 12, at the Polytechnic, Regent Street, W., when an address will be given by Mr. H. J. Mackinder on "The Regional Method in Geography." Tickets may be obtained from the honorary secretary of the Federated Associations, Miss R. F. Shove, 26 Blessington Road, Lee, S.E.

EDUCATIONAL and charitable institutions, says *Science,* have received 32,400*l.* by the will of the late Mrs. Frances E. Curtiss, of Chicago. Among the institutions which have benefited is Williams College, Williamstown, Mass., 5000*l.* Cooper Medical College, San Francisco, has received a bequest of 1000*l.* by the will of the late Mrs. Myrick. In connection with these bequests to higher education, it is interesting to note that our contemporary reports President Schurman, of Cornell University, as having said in a recent address: "I should like most to see at Cornell a score of research professorships with salaries, say 1500*l.* each, which would call for a capital of some 600,000*l.* or 800,000*l.*, a really small amount in this age of American multi-millionaires."

The issue of "The Public Schools Year Book" for 1910, which is now available, is the twenty-first, and the coming of age of this useful annual publication is marked fittingly by its adoption by the Headmasters' Conference as their official book of reference. The first part of the work is devoted to the proceedings of the Headmasters' Conference and to full information relative to the public schools. The second part deals with entrance scholarships at the public schools, entrance examinations to the universities, and the conditions of admission to the Navy, Army, Civil Service, and other professions, including engineering and chemistry. A general list of preparatory schools where young boys may be prepared for admission to a public school is also included. To parents proposing to send a boy to one of the public schools, the year book will prove invaluable, since the information respecting the organisation and instruction, fees and other charges, and so on, is just what they will require.

A recent table prepared for the London County Council Education Committee provides instructive particulars as to the ages of the boys and girls in the London secondary schools aided by grants from the Council. During the educational year 1909–10 there were in attendance in these schools 9244 boys and 5468 girls. Of the 9244 boys, 2131 were under 12 years of age, 1589 between 12 and 13 years, 1786 between 13 and 14 years, 1767 between 14 and 15 years, 1191 between 15 and 16 years, 465 between 16 and 17 years, 224 between 17 and 18 years, and 91 were more than 18 years. As regards the 5468 girls, 1467 were under 12 years of age, 896 were between 12 and 13 years, 863 between 13 and 14 years, 922 between 14 and 15 years, 805 between 15 and 16 years, 327 between 16 and 17 years, 154 between 17 and 18 years, and 34 above 18 years. In other words, only 780 of the total number of boys in the London secondary schools aided by the Council, or only 8·4 per cent., are above 16 years of age, and only 515 of the total number of girls in the schools, or 9·4 per cent., are above 16 years of age. It must be remembered that, with the exception of the greater public schools, the majority of the public secondary schools in London receive aid from the rates, and consequently it has to be admitted that the number of boys and girls receiving what may be called a complete secondary education is very small.

The London County Council aids upwards of fifty secondary schools in London. The grants are paid partly with the view of enabling the schools to accommodate a larger number of pupils than would otherwise be possible, and partly with a view of increasing the efficiency of the work. The income of the "aided" schools is derived from four main sources—endowment, Board of Education grant, fees, and grant from the London County Council. The total amounts of these sources of income for the educational year 1908–9 were as follows:—Endowment, 52,533*l.*; Board of Education grant, 49,818*l.*; fees, including fees of London County Council scholars, 114,334*l.*; and the Council's grant, excluding the fees of scholars, 41,415*l.*; making a total of 258,100*l.* It is estimated that during the present educational year the amounts will be:—Endowment, 53,190*l.*; Board of Education grants, 57,678*l.*; fees, 120,963*l.*; and Council's grant, 40,346*l.*; bringing the total up to 272,177*l.* In the case of each "aided" school, the Council requests the governors to submit a statement of receipts and expenditure for the completed year, and also an estimate of the receipts and expenditure for the coming year, and the grant made by the Council is estimated to be sufficient, together with endowments, fees, and Board of Education grant, to admit of the efficient carrying on of the school, and to provide a reasonable working balance throughout the educational year.

The prospectus for the current session of the Pusa Agricultural Research Institute gives particulars of the courses available for students in agricultural chemistry, economic botany, economic entomology, mycology, agricultural bacteriology, and agriculture proper. The work in each of these departments is respectively under the supervision of the Imperial agricultural chemist, economic botanist, entomologist, mycologist, agricultural bacteriologist, and agriculturist, who act under the principal as chiefs of the teaching staff. In the absence of experience of the class of student likely to be received, it has been found impossible to lay down a permanent syllabus of the training in each subject. The syllabuses are, for the present, tentative, and subject to the condition that time will not be wasted in taking students over ground that is already familiar to them. It may be remembered that the Pusa Agricultural Research Institute owes its inception to the generosity of Mr. Henry Phipps, who in 1903 placed at the disposal of Lord Curzon, then Viceroy of India, a donation of 20,000*l.* (which he afterwards raised to 30,000*l.*) with the request that it might be devoted to some object of public utility in India, preferably in the direction of scientific research. Part of this donation was devoted to the construction of a Pasteur institute at Coonoor, in southern India, and it was decided that the balance should be utilised in erecting a laboratory of agricultural research to form a centre of economic science in connection with that occupation on which the people of India mainly depend. This conception was subsequently enlarged, and the Government of India has now constructed a college and research institute, to which a farm of some 1300 acres is attached, for purposes of experimental cultivation and demonstration. The Pusa Institute is consequently in a position to enable students who have passed with distinction through a course at a provincial college, by means of a post-graduate course in one of the specialised branches of agricultural science, to qualify for the higher branches of agricultural work.

Replying to the toast of his health at the annual dinner of the Bristol University Colston Society on February 17, Sir William Ramsay, K.C.B., spoke of the administration of British universities. Professors should not, he said, be paid less than the average income obtainable in kindred professions. If a professor is paid at a much lower rate than he would obtain by entering some corresponding profession, it means that persons of one of three classes will occupy chairs. First a few men, from love of teaching or research, will carry on work on a pittance. Secondly, there are the men with a competence, who will take professional work for the love of it. They are few. The third result of underpayment is that professorial chairs will be filled with men of mediocre talent and capacity; students will suffer, and generations, as they succeed one another, will deteriorate. Scholarships, he continued, are mostly a waste of money. The bestowal of scholarships is not always a failure; but if granted as loans on the evidence of the power of application and good conduct, the money can, in most cases, be bestowed more profitably. What the public wants to buy, or should want to buy, is the educated brains of one who will in future prove useful to the State. The present method is one by which the article is uncertain and the price paid incommensurably high, owing to the high percentage of failures in attaining the standard of mind which the public has a right to demand. If the money distributed in scholarships were applied to the development of universities, England's universities would be rich.—The question of adequate remuneration for professors is to some extent a question of ways and means; until more money is forthcoming in this country for the purposes of university and higher education generally, there seems little possibility that the emoluments of men engaged in teaching and research will be increased. British universities seem unable to arouse the generosity of our men of wealth to the same extent as has been done in the United States, for instance. We notice in *Science* for February 11 that in one week donations were announced of 50,000*l.* to the Sheffield Scientific School of Yale University, 200,000*l.* for the establishment of a teachers' college, and 90,000*l.* for the general purposes of higher education. A few gifts on this scale would soon make it possible to remedy the defect to which Sir William Ramsay directs attention.

New science laboratories at St. Leonard's School, St. Andrews, N.B., were opened by Sir Ernest Shackleton on February 1. The building comprises two large laboratories each 34 feet by 30 feet, a lecture theatre to seat sixty pupils, a room for the preparation of experiments by the science mistresses, a dark-room for work in optics, a conservatory for botanical experiments, a cloak-room, and a spacious corridor, to be fitted with dust-proof museum cases. The chemical laboratory, which is also to be used for practical work in geography, is fitted with six benches, at each of which four girls work. The tops of the benches have been kept as clear as possible, carrying only Bunsen burners and two movable trays, each of which can hold ten reagent bottles. These trays, with the bottles they contain, fit into cavities in the sides of the benches, so that the tops can be cleared in a moment when required for practical geographical work. The reagent bottles are double-labelled, so that they can be used by two pupils working opposite each other. Attached to the front of the demonstrator's bench is a shelf, which hangs vertically when not in use. This has been designed for the purpose of holding the apparatus required for the lesson, and two girls from each bench come to this dispensing shelf and take from it all they require for their experimental work. The laboratories are both supplied with many light trays of varying sizes, each capable of holding a dozen beakers, flasks, burettes or pipettes, &c. These trays fit into the bench cupboards. Neither cupboards nor drawers have been set apart, as is usual, for the individual use of the pupils except in the case of the more advanced students, as experience has shown that they are apt to become receptacles for burnt matches, corks, soiled filter papers, &c. Placed in each stool recess is a shelf which holds a trough, test-tube rack, tripod, and retort-stand. The same principle has been observed in the fittings of the physical and botanical laboratory. The fume cupboards, of which there are four—two in the chemical laboratory, one in the physical laboratory, and one between the lecture theatre and the preparation room—are all supplied with both gas and water. The building is fitted throughout with electric light. In the lecture theatre there is an electric lantern, and a part of the cream-coloured wall acts as the screen, and allows a picture 10 feet square. This room is fitted with dark blinds, and ventilated, when these are in use, by means of an electric fan. In the conservatory are benches at which the pupils work when fitting up apparatus for botanical experiments. The usual precautions have been taken against accident by fire, and Minimax fire extinguishers stand in prominent positions.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 13.—D. P. **Phillips**: Re-combination of ions at different temperatures. The ionisation was produced in a layer of air of uniform thickness by means of a single discharge through a Röntgen bulb. The layer of air ionised was situated midway between two parallel electrodes, and was separated from each by a layer of un-ionised air. The quantity received by each electrode depends upon the field established between them, and from the variation of the quantity with the field the coefficient of re-combination can be calculated. By placing the pair of electrodes in a double-walled jacket the temperature was varied, and the coefficient of re-combination found at different temperatures. The values which were found are:—

Temp. Centigrade ...	16°	100°	155°	176°	273°
Coeff. of Re-combination	1·00	0·50	0·399	0·36	0·178

The value at the temperature of the room, *i.e.* at 16°, was taken as unity, and the other values were compared with this. The object of having the layer of ionised air separated from the electrodes by un-ionised air was to decrease the number of ions reaching the electrodes by diffusion, and so causing an apparent increase in the re-combination. With this arrangement the effect of diffusion would be to decrease the apparent re-combination. In order to test the magnitude of the error introduced by diffusion, the thickness of the ionised layer of air was altered, and the coefficient of re-combination determined for each thickness. At each temperature it was found that the coefficient of re-combination apparently falls off when the thickness of the layer is reduced below a certain value. Thus it was shown that in this experiment the diffusion was negligible up to 176° C., but that at 273° C. it probably caused a serious reduction in the apparent value of the re-combination.

Sir Edward **Thorpe** and A. G. **Francis**: The atomic weight of strontium. The principle of the methods employed consisted in determining the ratios of the weights of strontium bromide and chloride and of pure silver and of the silver halides respectively. The strontium salts, $SrBr_2$ and $SrCl_2$, purified by fractional crystallisation and precipitation, were fused in a stream of dry halogen acid and allowed to solidify in dry nitrogen. While the halides were still warm the nitrogen was replaced by dry air and the salts transferred to the weighing flasks. The fused salts were ice-like in appearance, and yielded perfectly clear neutral solutions in water. The silver needed to precipitate completely the halogen was dissolved in a specially devised burette, so contrived that the solution could be delivered without loss to the strontium solution. After eighteen hours the slight excess silver left in solution was titrated with a solution of strontium halide of known strength. Finally, the silver halide was dried, fused, and weighed. The apparatus was so devised that these operations could be done without removing the silver salts from the vessel in which it was formed. As an independent check, the ratios of $SrBr_2$ and $SrCl_2$ to $SrSO_4$ were also determined by converting the strontium halides into strontium sulphate by direct treatment with sulphuric acid. The possible sources of error are discussed, and all known corrections were applied. In all, six series of observations were made. The mean results are as follows:—

Series A.	$2Ag : SrBr_2$ (6 exp's.) ...	87·645±0·0037
,, B.	$2AgBr : SrBr_2$ (5 expts.)... ...	87·653±0·0045
,, C.	$2Ag : SrCl_2$ (6 expts.)	87·642±0·0017
,, D.	$2AgCl : SrCl_2$ (5 expts.)	87·645±0·0020
,, E.	$SrBr_2 : SrSO_4$ (3 expts.)	87·629±0·021
,, F.	$SrCl_2 : SrSO_4$ (4 expts.)	87·661±0·0078
Mean of A, B, C, D	...	87·646±0·0016
,, E, F	... ...	87·645±0·0107
,, A, B, C, D, E, F	... ...	87·646±0·0029

The authors adopt 87·65 as the definite value for the atomic weight of strontium—a number only 0·03 in excess of Richards's final value as given in the last report of the International Committee on Atomic Weights.

February 17.—Sir Archibald Geikie, K.C.B., president, in the chair.—E. **Marsden**: Phosphorescence produced by α- and β-rays.—Prof. E. **Rutherford**: Theory of the luminosity produced in certain substances by α-rays.—Dr. H. **Geiger**: The scattering of the α-particles by matter. In a previous note on the same subject experiments have been described which gave direct evidence of the scattering of the α-particles in passing through matter. These experiments have been continued with the object of determining quantitatively the amount of scattering under various conditions. In particular the influence of the thickness and nature of the scattering material and of the velocity of the α-particles has been studied in detail. With the exception of a few modifications, the experimental arrangement was the same as that employed in the preliminary experiments. A strong source of homogeneous α-radiation was placed at one end of a long tube, and the α-particles, after passing through a narrow circular opening, fell upon a zinc sulphide screen sealed to the other end of the tube. When the pressure inside the tube was very low the scintillations produced by the impact of the α-particles on the screen were confined to a very small area. When, however, the α-particles were intercepted by a thin sheet of metal, the scintillations were spread out over a much greater area, this being due to the scattering of the α-particles when passing through the metal sheet. The distribution of the scintillations over the screen was determined by counting them at different parts of the screen. From the distribution curve the most probable angle through which the α-particles were turned in passing through the metal sheet under investigation could be found. In all experiments the scattering was measured by this angle, and the following results were obtained:—(1) The most probable angle of scattering increases for small thicknesses approximately proportional to the square root of the thickness of matter traversed by the α-particle. For greater thicknesses the scattering angle increases more rapidly. (2) The most probable angle of scattering is proportional to the atomic weight of the scattering material. (3) The most probable angle of scattering increases rapidly with decreasing velocity of the α-particles.—Dr. H. **Geiger**: The ionisation produced by an α-particle. Part ii., Relation between ionisation and absorption. Experiments are described which were undertaken to measure the velocity of the α-particles after passing through various sheets of mica of known stopping power. A thin wire, which was made highly active by the deposit from radium emanation, served as source of radiation. The α-particles emitted from it passed through a narrow slit and produced a small line of scintillations on a zinc sulphide screen. The deflection of the line in the magnetic field amounted to 1 cm. and more, and could be accurately measured by means of a travelling microscope. The relative velocities found in this way when different sheets of mica were interposed were up to 6 cms. of the range in good agreement with those previously obtained by Prof. Rutherford by a photographic method. Great difficulties were experienced in observing the scintillations when the α-particles had to pass through a thickness of mica nearly equivalent to the range. It could, however, be shown that the velocity decreased rapidly towards the end of the range. The lowest velocity which was measured corresponded to 0·27 of the initial velocity. The α-particles had in this case to pass through a thickness of mica equivalent to 6·8 cm. of air. The experimental results could be represented with good approximation by the equation $v^3 = a\ (\mathrm{R} - x)$, where a and R are constants, R denoting the maximum range of the α-particles. The curve indicates that the velocity becomes zero at the end of the range. In the course of the experiments an investigation was carried out to see whether all the α-particles from radium C are emitted with identical velocities. The experiment showed that the variation in the initial speed, if any, was certainly less than 0·5 per cent., but that the α-particles acquired a slight difference in velocity in passing through air. Assuming that the ionisation produced by an α-particle is proportional to the expenditure of energy, the equation representing the ionisation at any point of the path can be deduced from the above equation for the velocity. Taking into account the slight variation of velocity in a pencil of α-particles at the end of the path, the theoretical ionisation curve agrees fairly well with the experimental.—H. C. **Greenwood**: The influence of pressure on the boiling points of metals. The present research is a continuation of a previous paper dealing with the boiling points of metals under atmospheric pressure. Previous work at reduced pressures has been strictly limited by the lack of any material capable of maintaining a vacuum at high temperature, being, in fact, confined, except for a few metals of relatively low boiling point like zinc, to some observations in a very high vacuum. For similar reasons nothing has been done on the effect of high positive pressures. The difficulties here indicated were avoided by arranging the whole furnace inside an enclosure in which the desired changes of pressure could be produced. Heating was effected electrically, and the temperatures were measured optically, while the actual boiling point determinations were made by a method of visual observation similar to that before used. Observations were taken at pressures ranging from 100 mm. of mercury to 50 atmospheres. The order of magnitude of the effects produced is shown by the following example:—The boiling point of bismuth under 102 mm. of mercury is 1200° C., and under 16·5 atmospheres 2060° C., a variation of 860° being thus produced. The boiling points of all the metals studied (bismuth, copper, lead, silver, tin, zinc) were found to show a closely similar dependence on the pressure.—A. O. **Rankine**: The viscosities of the gases of the argon group. The viscosities of the five gases—helium, neon, argon, krypton, and xenon—have been compared with that of air. The method used was that described in a paper recently communicated to the society. The principal advantage of this method is that it enables the viscosity of quite a small quantity of gas to be determined with considerable accuracy. The total volume of the apparatus used in this case was rather less than 6 c.c. The values found for the viscosities of helium and argon are in close agreement with those obtained by previous observers. The results for the remaining three gases admit of no comparisons, these being the first determinations. All five gases are more viscous than air, the ratios η/η air being as follows:—

He	Ne	A	Kr	X
1·086	1·721	1·220	1·361	1·234

The viscosity of neon at ordinary temperature is far higher than that of any other gas hitherto experimented upon, and krypton is next in order of magnitude. As the atomic weight increases the viscosity alternately rises and falls. If, however, the mean free paths are calculated by using Maxwell's equation, they are found to decrease regularly with increase in atomic weight. The paper also contains estimates of the relative sizes of the atoms and their densities, the calculations being based upon the kinetic theory of gases. The conclusions arrived at are that the densities of the atoms of neon, krypton, and xenon are the same, and three times as great as that of helium. The argon atom is nearly twice as dense as the helium atom.

Physical Society, February 11.—Dr. C. Chree, F.R.S., president, in the chair.—Prof. H. L. **Callendar**: *Presidential address.* The application of resistance thermometers to the recording of clinical temperatures. The objections to thermocouples are twofold. The E.M.F.'s developed are so small that the recording instruments must be very sensitive and therefore unsuitable for ordinary use. Serious difficulties arise with regard to the thermostat necessary to maintain one of the junctions of the thermocouple at a constant temperature. The chief difficulty in connection with the use of resistance thermometers lies in the heating effect of the current. It was pointed out that in platinum thermometry, to obtain accurate compensation for the resistance of the leads, it is necessary that the ratio arms of the Wheatstone bridge should be equal, and it was shown that this condition reduced the sensitiveness to be obtained by suitably varying the resistances by about 30 per cent. In joining up a bridge in work with resistance thermometers, Maxwell's rule for the positions of the battery and galvanometer which give maximum sensitiveness is seldom applicable. While Maxwell's arrangement actually gives the greatest sensitiveness, the heating effect of the current is so much greater that this more than counterbalances the increased sensitiveness. The problem to be solved in designing a suitable thermometer for clinical work is, with a given galvanometer and resistance-box, to find the resistance of the thermometer which will give the most accurate results for a given heating effect of the current. This is given by the equation $\mathrm{R} = 2\mathrm{G} + \mathrm{S}$, where G is the resistance of the galvanometer and S that of one of the ratio arms. It is important in the construction of a thermometer for clinical work to secure quickness of action and to reduce the heating effect of the current. An ordinary tube-form of thermometer is good for laboratory work with sensitive galvanometers, but it is unsuitable for use with recorders. The pattern of the thermometer must be suited to the purpose for which it is intended. Three types were shown, designed for mouth, rectal, and surface work. Continuous records obtained from a patient with a normal temperature were shown. The temperature is generally very steady if the thermometer does not shift or the patient get wholly or partly out of bed. The effects of external changes of temperature were also shown, and simultaneous records taken on different parts of the body illustrated the fact that the temperature does not vary in the same way at all places.

Royal Meteorological Society, February 16.—Mr. H. Mellish, president, in the chair.—E. **Mawley**: Report on the phenological observations for 1909. During the whole year wild plants came into blossom behind their usual time, the departures from the average being greatest in March and April. Such early spring immigrants as the swallow, cuckoo, and nightingale made their appearance rather earlier than usual. The only deficient farm crops were beans, peas, and hay. On the other hand, the yield of wheat, barley, oats, turnips, mangolds, and potatoes was well above the average, and more particularly barley and turnips. The crop of apples, pears, and plums was under average, whereas that of raspberries, gooseberries, currants, and strawberries, taken together, was fairly good. As regards the farm crops, this was the fourth year in succession in which the yield has been above average.—Colonel H. E. **Rawson**: The North Atlantic anticyclone. The author has examined the "Synchronous Weather Charts of the North Atlantic" published by the Meteorological Office for the months of September, 1882, to August, 1883, and has analysed the tracks of the centres of high-pressure areas during that period. He finds that it is very rare for an individual system which has traversed the American continent to cross the ocean from land to land. In every month centres of high areas which have drifted across America and have travelled out on to the ocean are found coalescing there with one another or with the centres of the persistent Atlantic anticyclone. From mid-February to mid-September the charts indicate that on arrival on our coasts systems extend westwards, and their centres reverse their easterly movement and drift to the west, while in June and July the centres of high areas form over the ocean within the Atlantic anticyclone rather than drift into it from the American continent.

Institution of Mining and Metallurgy, February 17.—Mr. Edgar Taylor, president, in the chair.—Bede **Collingridge**: Errors due to the presence of potassium iodide in testing cyanide solutions for protective alkalinity. The results of experiments made by the author show that potassium iodide exercises an important influence on cyanide solutions, especially on solutions which contain no protective alkali, since in testing these in the presence of potassium iodide they show protective alkalinity. This fact is of considerable interest in cyanide plants, because cyanide decomposes more rapidly in solutions deficient in protective alkalinity than in those protected by an alkali, and the method adopted by the author for testing without potassium iodide would therefore imply a marked saving of cyanide in the case of large plants.—A. R. **Andrew**: The detection of minute traces of gold in country rock. In the course of investigations made for the purpose of determining the presence, or otherwise, of minute traces of gold in the shales and greenstone of Merionethshire, the author found that he was unable to believe in the trustworthiness of the methods usually adopted for that purpose, particularly as regards the possibility of obtaining litharge or any sort of lead absolutely free from gold and silver. On that account he claims that no credence should be given to any alleged detection of minute traces of gold in country rock unless accompanied by a full account of the means by which the purity of the litharge is assured.—W. A. **MacLeod**: The surface condenser in mining power plant. The author conducted a number of tests on the winding engines of a mine with which he was connected, the results of which are embodied in this paper, together with a vast amount of other information concerning the relative consumptions and efficiencies of condensing and non-condensing engines. He found that the employment of condensers was distinctly beneficial in both respects, even under the intermittent conditions attaching to most mining power plants, and the results of his investigation have enabled him to determine with some exactness the leading features to be emphasised in the laying down of a condensing plant suitable for work of a more or less intermittent nature, as is the case of winding engines.

CAMBRIDGE.

Philosophical Society, January 24.—Dr. Hobson, vice-president, in the chair.—R. R. **Mines**: The relative velocities of diffusion in solution of rubidium and cæsium chlorides. The rates of diffusion of salts into a gelatine jelly were compared by measurement of the progressive changes in the electrical conductivity at a fixed distance below the surface of the jelly when in contact with decinormal solutions of the salts. The concentration of salt corresponding to each reading was obtained from Kohlrausch's tables. Experiments carried out with lithium, sodium, and potassium chlorides gave results which agree with the values found by previous observers for the relative rates of diffusion of these salts in aqueous solution. This was considered to justify the extension of the method to rubidium and cæsium chlorides, as to the rates of diffusion of which no data were available. Rubidium chloride was found to diffuse slightly faster than potassium chloride, and cæsium chloride slightly faster than rubidium chloride.—L. **Southerns**: Experimental investigation as to dependence of the weight of a body on its state of electrification.—Miss D. B. **Pearson**: Note on an attempt to detect a difference in the magnetic properties of the two kinds of ions of oxygen.

PARIS.

Academy of Sciences, February 14.—M. Émile Picard in the chair.—G. **Lippmann**: A seismograph with a liquid column. A T-tube, full of water, is connected at each end with two basins of the same liquid. The changes of level in the arm of the T-tube are indicated by a thin disc of mica, connected through a suitable mechanism to a mobile mirror. To avoid friction, the disc does not touch the sides of the tube. Owing to this, slow changes of the vertical are not recorded by the instrument. The apparatus has the advantage that its period is invariable, depending only on the dimensions originally chosen, and the preliminary adjustments are much simpler than in the ordinary form of seismograph.—The perpetual secretary read a telegram from Dr. Charcot, summarising the work achieved by the Antarctic expedition.—Ernest **Esclangon**: The transformations of the Innes comet (1910*a*). Two diagrams of this comet are given, showing its appearance on January 22 and 30. Although there is no doubt that real transformations of considerable magnitude took place in this comet between the above dates, it is shown that an important part of the modifications observed, especially as regards the shape, is to be attributed to the changes in the angle at which it was observed. Observations of position are given for January 22 and 30, the conditions being especially good, and for February 9.—J. **Comas Solá**: The figure of the comet 1910*a*. Photographs were taken daily commencing January 20, and the resulting negatives discussed.—M. **Borrelly**: Observations of the comet 1910*a*, made at the observatory of Marseilles with the comet finder of 16 cm. free aperture. Positions are given for February 4, 5, 7, 8, 10, and 11.—Émile **Borel**: The definition of the definite integral.—J. **Le Roux**: Positive quadratic forms and the principle of Dirichlet.—Farid **Boulad**: The disjunction of the variables of equations nomographically rational of superior order.—Carlo **Bourlet**: The resistance of the air.—Mme. P. **Curie** and A. **Debierne**: Polonium. Starting with several tons of uranium mineral residues a preliminary treatment with hydrochloric acid furnished about 200 grams of material with an activity about 3500 times that of uranium, this activity being due to polonium. The hydrochloric acid solution was treated with ammonia to eliminate copper, the hydrates boiled with soda to dissolve lead, and then further treated with ammonium carbonate to dissolve uranium. The final residue of insoluble carbonates, obtained after several repetitions of these processes, were dissolved in hydrochloric acid and treated with stannous chloride. The original activity was concentrated in the final precipitate, which weighed about 1 gram. This was re-dissolved in hydrochloric acid, precipitated with hydrogen sulphide, the sulphides washed with sodium sulphide, and re-dissolved and again precipitated with stannous chloride. The final product of this lengthy series of operations weighed some milligrams, and was shown by spectrum analysis to contain mercury, silver, tin, gold, palladium, rhodium, platinum, lead, zinc, barium, calcium, and aluminium. The further purification presented great difficulties, but by electrolysis the activity was concentrated into about 2 milligrams of material. Activity measurements proved this to contain about 0·1 mgr. of polonium, and this is the quantity which ought to be found according to theory in two tons of a good pitchblende. Some lines in the spectrum are given which are probably due to polonium. The production of helium was proved, amounting to 1·3 cubic millimetres after 100 days, the theory requiring 1·6. An abundant disengagement of ozone was generally found near the substance.—L. **Décombe**: The measurement of the index of refraction by means of the microscope. A modification of Brewster's method. The liquid is placed between a plane and a plano-convex lens. In monochromatic light the refractive index can be determined to about 0·001.—P. Roger **Jourdain**: The alumina arising from the oxidation of aluminium amalgam in air.—Marcel **Delépine**: The dimeric aldehyde of crotonic aldehyde and the corresponding acid. A method of obtaining this substance with fair yields has been worked out, and the corresponding acid prepared and described.—J. **Bougault**: The action of nascent hypoiodous acid on the unsaturated acids: α-cyclogeranic acid.—Frédéric **Reverdin**: The action of concentrated sulphuric acid on some aromatic nitramines.—L. **Barthe**: The action of sulphosalicylic acid on trisodium phosphate.—. **Chevalier**: The forest resources of the Ivory Coast: the results of the scientific expedition to western Africa. Wood, rubber and oils.—L. **Blaringhem**: A new form obtained after mutilation, *Nigella damascena polycephala*.—J. B. **Gèze**: The agricultural development in the Bouches-du-Rhône of a spontaneous species of Typha (*T. angustata*) not previously noted in France.—L. **Léger** and Ed. **Hesse**: Cnidosporidia and the larvæ of Ephemera.—L. **Joubin**: A young Spirula.—Mme. **Phisalix**: The physiological action of the mucus of batrachians on these animals themselves and on snakes. This action is the same as that of snake poison.—L. **Jammes** and A. **Martin**: The adaptation of parasitic nematodes to the temperature of their hosts.—E. **Grynfeltt**: The tensor muscle of the choroid in teleosteans.—J. **Thoulet**: The genesis of the submarine rocks known under the names of *mattes*.—André **Brochet**: The relation between the radio-activity and richness in dry extract of the thermal waters of Plombières.—Louis **Besson**: A sort of white rainbow observed at Paris.

DIARY OF SOCIETIES.

THURSDAY, February 24.

Royal Society, at 4.30.—Colour-blindness and the Trichromatic Theory of Colour Vision: Sir William Abney, K.C.B., F.R.S.—Contributions to the Biochemistry of Growth: (*a*) The Total Nitrogen Metabolism of Rats bearing Malignant New Growths: (*b*) Distribution of Nitrogenous Substances in Tumour and Somatic Tissues: W. Cramer and H. Pringle.—The Alcoholic Ferment of Yeast Juice: Part V., The Function of Phosphates in Alcoholic Fermentation: Dr. A. Harden, F.R.S., and W. J. Young.

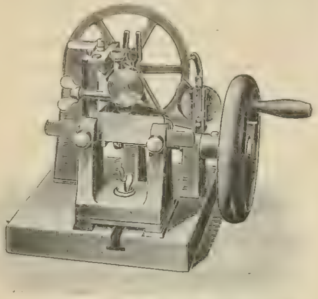
OFFICE: ST. MARTIN'S STREET, LONDON, W.C.

LEITZ' MICROTOMES

The steady and increasing demand for good microtomes has induced us to bestow closer attention upon this branch. We have accordingly instituted a separate department for the construction of Microtomes, adapted to the most exacting requirements of the present day.



THE LEITZ MINOT MICROTOME.

Specially designed for cutting extra thin serial sections, and continuous ribbons.

The carriage moves freely, yet without the slightest play. The universal clamp-holder is constructed on the principle of Hooke's key.

PRICE (without knife or ribbon conveyor), **£8.**

Many other patterns, from 15s. each.

E. LEITZ, OXFORD HOUSE, 9 OXFORD ST., LONDON W.

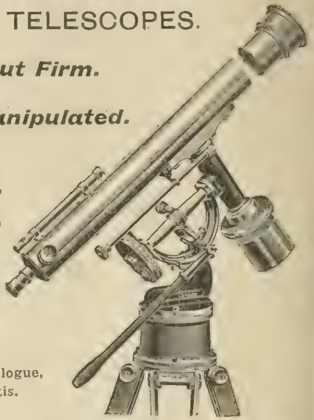
Agents in all University Centres.

J. H. STEWARD'S
PORTABLE EQUATORIAL MOUNTING

FOR 3″ TELESCOPES.

Light but Firm.

Easily Manipulated.



STAND AND MOUNTING,

£15 15s.

or

with 3″ Telescope,

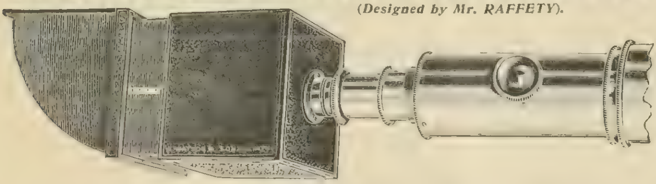
£30.

Illustrated Catalogue, Part I., Gratis.

406 Strand & 457 West Strand,
LONDON.

NEW HELIOSCOPE PROJECTION CAMERA

(Designed by Mr. RAFFETY).



For the observation of an enlarged erect image of the solar disc.

Attaches to the Eyepiece, and is complete with Rotating Diaphragm with coloured discs. The image is viewed on a glass screen coated with a practically grainless film, enabling the projected image to be viewed without transposition. Faculæ and the varying brightness of different parts of the photosphere can be easily seen.

PRICE complete, **30/-**; postage, 8d.

For full particulars of the above and of Watson's Astronomical Telescopes send for Catalogue 6 N gratis on application.

W. WATSON & SONS, Ltd. (Established 1837), 313 HIGH HOLBORN, LONDON, W.C.
Works: BARNET, HERTS. Branch: 16 FORREST ROAD, EDINBURGH.
Depots—2 EASY ROW, BIRMINGHAM; 78 SWANSTON STREET, MELBOURNE, AUSTRALIA.

A NEW DALLMEYER STIGMATIC.

The Carfac Series IV f/6.3 is a low priced rapid anastigmat giving good definition at full aperture. Particularly suitable for hand cameras of all types.

By a great simplification in design the manufacturing cost has been reduced, with the result that this lens is remarkably low in price. Moreover, though containing only four glasses, the front combination may be used alone and gives pictures nearly three times the ordinary size, whilst the back alone with short extension gives pictures nearly half as large again as the complete lens.

WHY NOT SEE IT AT OUR SHOWROOMS AT 25 NEWMAN STREET, OXFORD STREET?

BRITISH MADE. *BRITISH MADE.*

DALLMEYER ESTABLISHED LENSES 1860 CAMERAS LONDON

Three Lenses in One.

PRICES: ¼-plate, £3 5×4 and Postcard, £3 10 0
